PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 1.

JANUARY 2, 1904.

\$5.00 YEARLY.

Pneumonia a "Reportable" Disease.—Such is the amendment to the sanitary code of New York City. The order is said to be the first in the records of health departments anywhere, and marks both a recognition of the infectious nature of the disease and of its increased ravages in late years. These conclusions have long and persistently been emphasized by the Health Department of Chicago, but there has generally been an altogether too slow decision to make the administrative order to report cases of pneumonia, just the same as those of measles, smallpox, scarlet fever, etc. At last the logical and necessary step has been taken, and other cities will doubtless soon follow the example of New York. The increasing prevalence of the disease in that city is shown by the following excerpt from the report of the register of records:

PNEUMONIA.					
Week ending					
	Nov. 14.	Nov. 21.	Nov. 28.	Dec. 12.	Dec. 19.
1902.	113	119	116	105	120
1903.	138	158	164	172	188

If such ratios obtain in general, there can be no question of the infectiousness of pneumonia, and of the necessity of notification and public control.

The "unionized funeral," such as has recently been illustrated in Chicago, possibly relates to medicine and physicians only indirectly, but in conjunction with the unionized doctor, the matter comes closely home to the profession. Whatever opinion one may have as to the relations of "capital and labor," they should certainly end with the dead and with those bereaved, and as certainly with the prevention of death. No better way at least, exists for destroying whatever sympathy may exist for workmen, the drivers of carriages and hearses, for example, than the continuance or repetition of the indignities which these men have carried on. Why not also union-made hearses and coffins, union-grown flowers, and union-dug graves? If unionized medical men, why not unionized ministers and priests? and churches? and diseases? There is no limit, logically, until every act of life, every instrument and drug in medical and surgical practice, and every hygienic measure, shall be brought under the union label and rules. Are we to have unionized hospitals? The medical profession and the dissemination of medical knowledge is already sufficiently handicapped and taxed by the typographers'

unions, which make every medical book and periodical cost more than it should, and which are, in fact, against the true interests of the workman and the typesetter himself. The tribute the profession is forced to pay to moneyed and commercial interests is already high enough without additional disuniting unionism.

Locomotive whistling has in our country become a menace to public comfort, sleep, and health. We do not mean the whistling of the engineers at grade-crossings in the country (which should also be done away with by abolishing the grade-crossings), but that of the switching engines, in or near towns and cities, at work all night, and which is done solely for the convenience of the trainmen. In no other country in the world is this nuisance allowed. In some of our cities stringent laws exist against it, as *e. g.*, in Philadelphia, but they are utterly ignored by the officers sworn to execute the law. The officials seem to prefer to execute the people. There can be no doubt that a majority of the people of cities, especially in summer, are injured in health because of loss of sleep, and that the sick and convalescent are dangerously harmed. All physicians know how necessary sleep is to the maintenance and reestablishment of health. The whistling is wholly unnecessary and often is against the rules of the company. Thus because it is "nobody's duty" to stop it, a half dozen workmen disobey the railway rules and the city ordinances without check. But it is somebody's duty—and that somebody is the local Board of Health. Protests from physicians would soon prove effective—and surely from their patients!

Responsibility for the Typhoid Epidemic at Butler.—It is an old story to the medical profession, but it is well to have it laid before the lay and engineering world so admirably as has been done by Dr. George A. Soper in the *Engineering News*. Owing to the failure of a dam, the water had been drawn since last August from the Connoquenessing Creek at a point at which it was obviously polluted. The supply had been filtered until October 20. On that date the filters were shut down, and kept out of service until a pipe connection could be made between some new pumps and the basin for filtered water. It could not be ascertained that any warning had been given to the public that the water

from the polluted creek was being pumped during this time, and it is improbable that the water company considered that it was dangerous for drinking purposes. In fact, the families of some of the employes of the water works were among those most afflicted with typhoid fever. The filters were out of service from October 20 to 31. The epidemic broke out about November 2. The report is an exhaustive review of the municipal conditions at Butler, its system of water supply, the filter plant, sanitary condition of the sources of water supply, and the course of the epidemic. It says that it is still too early to take the full measure of the epidemic, but the most reliable statistics place Butler above all other epidemics of typhoid fever of recent times in the number of cases which have occurred. Following are the data of the most extensive typhoid epidemics which have taken place in the last twenty-five years:

Place.	Date.	Popula- tion.	No. of Cases.	No. of Deaths.	Cause.
Caterham, Eng.	1879	5,800	552	21	} Water Supply
Plymouth, Pa.	1885	8,000	1,104	114	
Ithaca, N. Y.	1903	13,000	1,300	78	
Butler, Pa.	1903	18,000	*1,270	*56	

* To December 17.

Dr. Soper says that—

Judging from all the evidence in hand, Butler might almost as well have had no local Board of Health as the one which accepted the grave responsibilities of that position. In fact, perhaps, it would have been better off without than with the existing Board, upon which more or less reliance was placed, until it showed its utter incapacity. Finally, we wish to repeat our warning of a week ago, that hundreds of communities in this country are liable any day to be overwhelmed with the horrors of such an epidemic as that at Plymouth, or Ithaca, or Butler. These communities merely had to pay the penalties for impure water and lax sanitary administration which other communities equally neglectful have been fortunate enough to escape.

"Graft" in the nursing and medical professions, according to the fashion of the day, is appearing. A confidential letter lies before us from a trained nurse to a physician offering him "a liberal fee" for every patient he may place her in charge of. Similar abuses among medical men themselves, and publicly exposed trade discounts from instrument-makers, druggists, undertakers, etc., make one shrink with shame at the mere knowledge of such propositions. But as pertaining to the nurses the multiplication of quack nursing schools and the frank placing of their ideals upon a purely financial basis (or with a worse gloss of hypocritical sentiment) emphasizes the need of organization and higher standards of education which are now being so eagerly sought by all honorable and well-trained nurses.

Abuse of Medical Certificates.—Physicians who certify to the usefulness of new devices or preparations—or devices or preparations alleged to be new—are always liable to have their certificates abused, as in a circular before us. In this advertisement professional recommendations of a presumably convenient form of formaldehyde generator are twisted into endorsements of an "infallible remedy." In large headlines it is said

that the device absolutely and permanently cures Hay-fever, Consumption, and "all Nose, Throat and Lung diseases" in two days! Two years would be a sufficiently moderate claim. But long before two years had elapsed the precious "guarantee" would be demanded—so two days is the limit in which dupes can get money back. And men with M.D., LL.D., etc. after their names write to the inventor of this fraudulent "Sure cure for Consumption" in praise of his wares! It is unfortunate for honorable manufacturers, and there are of course many such, that the scoundrelism of others must more and more prevent physicians from commending, in any quotable manner, even the best things. Too great caution cannot be urged as to testimonial giving.

A new method of "division of the spoils," devised by a manufacturer, is that by means of the "coupon label." In a private and confidential letter to one of our subscribers, a manufacturing firm, after extensively extolling the preparation as the greatest and surest cure for many diseases, says:

A novel feature of our proposition to the medical profession is the coupon label, a sample of which we are enclosing. These coupons are detached, returned by the dispensing druggist, to the prescribing physician, by whom they are signed and returned to us, and redeemed at the rate of 10%, either in cash, or if you prefer, we will exchange them for any medical or nonmedical periodical published. What we have to pay for constant sampling we would rather give to the physician in dividends.

In connection with the letter are testimonials from "physicians" to the virtues of the drug. The investment of money in the plan prevents the answer that there are surely not enough of that kind of medical men to make such a method of doing business a profitable one. Do such schemes really "pay"?

The exclusion from the public schools of unvaccinated children has been decreed by the Health Department of Chicago. The order pertains especially to the children of the Dowieites, but is, of course, general in its terms, and thus affects the antivaccinationists of all kinds. The general overseer of Zion has made his followers believe that vaccination does not prevent smallpox. The Zion children will be segregated by requiring all pupils to present certificates of vaccination. The names and addresses of all children who fail to comply with the order will be forwarded to the Health Department. It is time that all Boards of Health should come to a similar conclusion, and it is the best way to meet the (unconscientious) "conscientious objector." It is, of course, the first step, and must logically and practically be followed by the last—compulsory vaccination of every child, man, and woman of the community. Public feeling and intelligence have at last reached the clearness to warrant the safe promulgation and thorough administration of such laws, and every day demonstrates the folly and expense in lives, suffering, and money of further delay in proceeding to the realization of both policy and duty.

Prehistoric Trephining.—Since the publication of the original observations of M. Broca on the subject of trephining in prehistoric times, a vast mass of evi-

dence has been accumulated in connection with the question which, collectively, goes to show that in latter-day surgery, as in prechristian Indaic philosophy, "there is nothing new under the sun." The great French anthropologist informed his readers that "until quite recently trephining of a primitive kind was in use among some of the South Sea Islanders for the treatment of epilepsy, insanity, and even headache; and the operation was done by scraping with a piece of flint or broken glass, when the latter was to be had from Europeans. In much the same way and with similar instruments the operation was done in the neolithic or polished-stone period, the age following the so-called quaternary, and preceding the bronze epoch. This period corresponds with the burial in dolmens, the use of agriculture and the employment of domestic animals, and the making of hatchets of polished flint, though rough-chipped instruments were still in use." The investigations of Broca and Prunèires in this connection convinced those observers that there had been a practice of postmortem, as well as of antemortem, trephining among those primitive islanders. It also appeared that the antemortem (surgical) operation had in nearly all their specimens been performed during the first few years of life. Also, that the posthumous operation had been performed only on those who had survived the former one. In many of the skulls which bore unmistakable evidence of subsequent development, it was found that a number of pieces of bone had been chipped off from the margins of the orifice. Some of those pieces were actually found. They had been shaped as amulets or perforated for purpose of suspension. Broca's explanation was found by referring to the primitive notion that all very pronounced head symptoms—such as those of insanity, melancholy, epilepsy, and even violent headache—were caused by demoniacal possession; that, accordingly, an artificial cranial orifice was made to promote the exit of the evil spirit; and that for the remainder of life the individual would be regarded as a sacred personality, with the superadded distinction that his relics after death would be greedily sought as "charms" and miraculous agents for the warding off or the expulsion of evil spirits. But the sifting and weighing of the evidence was further complicated by the fact that in all the cases of this postmortem trephining noted by these distinguished observers, a certain proportion—usually about one-fourth—of the circumference of the original opening had been left undisturbed; and that the vacancies left by the removal of the amulet material had been, in each specimen, approximately filled by similar pieces from some other skull. In discussing this very curious point, M. Broca expands his hypothesis by offering the fact as an indication—the earliest that he knew of—of a belief in an existence after death. It proves, to his mind, that those primitive trephiners believed that the "individuality" was maintained after the death of the body; in religious deference to which faith they would not rob him "in the other life of the glorious evidence of the operation which he had undergone in his youth." So that it would actually appear that the twentieth century Anglo-Saxon problem of the survival of "human personality" had been

attacked and solved—to their own satisfaction—by those far-off, prehistoric savage islanders!

Primitive Trephining in America.—The first recorded specimen found on this side the Atlantic was taken from the Tucay cemetery, in the Valley of Yucay, Peru. American experts pronounced the specimen to be of (at least) precolumbian date. The skull was afterward forwarded to M. Broca. The result of his examination was that we are "authorized to conclude that there existed in Peru—before the European epoch—an advanced form of surgery." Dr. Robert Fletcher, in discussing this subject, observes that "the numerous specimens which have been found in Michigan suggest several inquiries. Many more prehistorically trephined skulls have been found in Michigan than in any other State of the Union." Illinois and Ohio come next in order in the number of such discoveries. The conclusion arrived at is, that either these States have made more explorations than the others, or that the valley of the Great Lakes contained a race of people who practised trephining while the surrounding tribes did not, as the Kabyles of Northern Africa do at the present day. Michigan appears to have fewer mounds than the other States of the Union. But although the mounds have been everywhere examined, there have been very few trephined skulls found outside this region. It is a remarkable, and very interesting fact, that the artificial openings in all the American skulls have been found near the vertex. "They have rarely shown any evidence of cicatrization, and for those reasons are generally believed to have been trephined for religious rather than for surgical purposes." However this may be, the net result of the investigations hitherto made has been to lead to the conclusion "that the valley of the Great Lakes once contained a people who practised surgical trephining." It has been critically observed that the incisions found in the wall of the "Inca skull" from Peru appear to have been made with some cutting instrument, "something like an engraver's burin, and not with a saw." In a discussion which recently took place on this subject in London, Sir Victor Horsley showed photographs of three American specimens of skulls so treated. He regarded the traces as those of saw-cuts. They were all in the frontal region; and the conditions, taken in connection with the other evidence now available, gave, according to this observer, "reasonable ground for believing that the Peruvian operation was probably done for headache."

The Primitive Trephining of the Savage of the Present Day.—The very interesting fact that trephining practices, such as would appear to have been used in prehistoric times, are at present familiarly carried out in far off Pacific and South Sea Islands, has recently been demonstrated before the Anthropological Institute of Great Britain and Ireland. In New Britain, the operation is performed for fracture only. The instrument used is formed from a piece of shell or a flake of obsidian, and the operator is the wizard or "tena-papait" of the tribe or district. A blow of a sling stone is the usual cause of the fracture which calls for the operation; the

sling, being the most formidable weapon used by the pugnacious natives in their tribal fights; and "a smooth stone as large as a pullet's egg being thrown with moderate accuracy, but considerable force." Death almost invariably ensues in cases which are not promptly treated. We are also told that, "Injury, caused by the stoneheaded club, is almost instantly fatal, but the flat two-edged club is not so deadly, and permits of an occasional operation. The procedure is after this manner: "A V-shaped or Y-shaped incision is made over the seat of fracture, and while assistants hold back the scalp, any loose fragments are picked out with the finger-nail. The other portions involved in the fracture are then scraped, cut, and picked away, leaving the brain exposed to the size of half a crown, then, all loose pieces having been removed, the scalp is carefully laid down, and the wound bandaged with strips of banana stalk about four inches wide. These strips are, when dry, of a spongy nature, the water which formerly filled the cells being replaced by air; moreover the inner surface is silky to the touch, and forms an admirable dressing for tender surfaces. It is astringent in its action, and nonabsorbent, all discharge escaping below the bandage. Sometimes a few bruised leaves are applied before bandaging. The patient is generally insensible from the time of the injury, and if consciousness returns during the operation, soon faints away again. In five or six days the bandages are renewed, and in two or three weeks a complete recovery is the result. The number of deaths is about 20%, most of these resulting from the first injury, and not from any complication after the operation. "Nearly all the deaths take place during or immediately after the operation, and I am assured that if a patient once becomes conscious he never fails to make a good recovery." The writer of this report recently discovered that in New Ireland the operation is also performed in cases of epilepsy, and for some cases of insanity which are attributed to pressure on the brain. He has in his possession one skull "which has been successfully trephined in no less than five places, the man meeting his death some years after the last operation by a blow from an axe." This man had suffered from severe, local throbbing headache. Although the cure does not appear to have been forthcoming, the operation was, in each instance, "successful." He reports a cure—at least up to date—of an epileptic patient. On Gerrit Demp Zeland, and in the central part of New Zealand, the usual form of operation—often performed for throbbing headache—consists of cutting 2 or 3 channels, in a vertical direction, on the frontal bone, each three or four inches in length.

Mortality in Pittsburg.—During the week ended December 5, 154 deaths occurred in Pittsburg; of these 36 were due to pneumonia, 11 were due to pulmonary tuberculosis, 11 to typhoid fever, 6 to diphtheria, and 6 to smallpox.

Many Rejected from Navy.—According to the report of the Surgeon-General of the United States Navy for the year 1902 the total number of applicants examined for service in the United States Navy was 31,826. The number rejected per 1,000 for all cases was 488.62; the number rejected per 1,000 for color-blindness was 27.9. It would appear from this that nearly 50% of those making application for service in the United States Navy are rejected for cause, and that between 2% and 3% are rejected not for ordinary defects of vision, but for color-blindness.

AMERICAN NEWS AND NOTES.

GENERAL.

Resignation of Instructor.—Dr. Augustin H. Goelet has resigned the chair of gynecologic electrotherapeutics in the International Correspondence Schools of Scranton, Pa., to take effect January 1, 1904.

Camp for Tuberculous Naval Employees.—The *Army and Navy Register* states that an experimental camp for the treatment of tuberculous employees has been established at Pensacola, Fla. This is the beginning of an attempt to find the best location for a permanent camp. Formerly those in the Navy who were stricken with tuberculosis were promptly discharged with a pension. Now they are kept in the service and treated by modern methods. There are now 6 patients at the temporary camp and this number will soon be increased to 25.

Against American Congress on Tuberculosis.—The Council of the Indiana State Medical Association in session at Indianapolis, December 17, 1903, passed a resolution stating "That the Council of the Indiana State Medical Association, representing the medical profession of Indiana, believing that the so-called American Congress on Tuberculosis, organized by Clark Bell, Esquire, of New York, is not a body which is representative of the medical profession or of the best scientific thought of this country, deems it inadvisable and inexpedient for the Indiana State Medical Association to be represented in said Congress, and that we advise our President to notify Mr. Bell that he declines to appoint delegates to it." The Secretary of the Council was instructed to furnish a copy of the resolution to the medical press and to the Secretary of State Hay who has been specially importuned to lend official aid and support to the movement.

Physicians for Philippine Service.—The United States Civil Service Commission announces that on January 27-28, 1904, an examination will be held to secure eligibles from which to make certification to fill vacancies in the position of physician in the Philippine Service, at salaries ranging from \$1,200 to \$1,800 per annum, and other similar vacancies as they may occur in that service. The examination will include the following subjects: Letter-writing, anatomy and physiology, chemistry and materia medica, surgery and surgical pathology, practice and special pathology, bacteriology and hygiene, obstetrics and gynecology, and experience. Questions on practice and special pathology will be principally upon tropical diseases. At least one year's experience in hospital work, or in the Philippine Islands as assistant surgeon in the U. S. Army, is prerequisite. The age limit is 20 to 40 years. Two days will be required for the examination. Examinations will be held in one or more places of practically all the States of the Union. In Pennsylvania they will be held at Bellefonte, Bethlehem, Harrisburg, Philadelphia, Pittsburg, Scranton, Warren, and Williamsport.

To Combat Yellow Fever in Mexico.—News from New Orleans under date of December 15, says: Dr. George R. Tabor, State health officer of Texas, wants the 3 States of Alabama, Louisiana, and Texas, which were the parties to the Galveston conference, to agree upon uniform regulations of quarantine against yellow fever, in Mexico, and he is going to Washington to confer with Surgeon-General Wyman, of the United States Public Health and Marine-Hospital Service, and ask for the cooperation of the national body. Speaking about his plans, Dr. Tabor said: "I want the United States Public Health and Marine Hospital Service to take up the question with the Superior Board of Health of Mexico to try to exterminate yellow fever not only from the Rio Grande, but in all Mexico. I have no doubt that it can be done there as it was done in Havana. Yellow fever is more prevalent in Mexico this year than it has been in past years, and in Vera Cruz, where it always exists, there were more cases than at any time in the last 10 years, but conditions are considerably improved now, and in Monterey, where there were several cases this summer, it is reported that not a case exists at the present time."

Statistical Report of the Health of the Navy and Marine Corps for the Year 1902.—The health record of the Navy and Marine Corps for the year 1902 was good; the ratio of admissions to the sick list per 1,000 being slightly greater than for the year 1901, but much less than the average for the 7 preceding years. During 1902 the average strength of the active list was 31,240, an increase of 4,367 over the previous year. The total number of admissions for all causes was 22,645, the ratio per 1,000 of strength being 767.63, as compared with a ratio of 766.75 for the previous year, and 801.44 for the 7 preceding years. There were 18,882 admissions for disease, and 3,763 for injury, giving ratios of 640.07 and 125.56. The corresponding ratios for the year 1901 were 652.96 and 113.78. The daily average of patients was 1,025.93, and the ratio per 1,000 of strength 34.77, the corresponding data for the previous year being 887.21 and 33.99. The total number of sick days was 374,466, or an average of 12.05 sick days for each man in the Navy and Marine Corps, with an average duration of 16.53 days' treatment for each case. During 1901 the average number of sick days was 12.40, and the

average duration of treatment per case was 16.12. The number of persons invalided from the service (including retirements of officers for disability and transfers to hospitals for the insane) was 1,144, giving a ratio of 37.81 per 1,000 of strength. The corresponding figures for the year 1901 were 1,003 and 37.32, respectively. The ratio for the year 1902 is considerably higher than the average ratio for the period of the 7 preceding years—26.17—due, no doubt, to the large number of recruits now being received to fill up the increased complement of the Navy and Marine Corps. The discharges for disability were divided into 1,001 for disease and 143 for injury, with ratios per 1,000 of strength of 33.09 and 4.72, respectively. The corresponding figures for 1901 were 875 and 128, respectively, with ratios of 32.56 and 4.76. Two hundred and eleven deaths occurred during the year, the mortality per 1,000 of strength being 4.13 for disease and 2.62 for injury; total, 6.75. This ratio (6.75), while slightly higher than that of the previous year (6.18), is still less than the average for the 7 preceding years. Twelve deaths from starvation (occurring during the campaign in Samar, in the marine detachment) and 6 from cholera, are unusual causes that swell the death list for this year. Among the causes of admission to the sick list, malarial diseases stand first with 1,408 admissions, wounds ranking second with 942 admissions, while epidemic catarrh, which has headed the list for the 2 preceding years, falls to third place with 877 admissions. Dengue fever adds 531 admissions to malarial affections. Rheumatic and diarrheal affections rank next in prevalence with 799 and 783 admissions, respectively. Epidemic diseases increased somewhat over 1901, the admissions for the most prevalent being 681 for 1902 to 527 for 1901. The number of admissions for mumps and measles was almost twice as great as for 1901, while the admissions for diphtheria and rubella are considerably less. The admissions for smallpox are practically the same. The admissions for the epidemic diseases are: Mumps, 330; measles, 245; diphtheria, 65; rubella, 48; smallpox, 23. Venereal diseases still cause a decided loss of efficiency, the total admissions for the year being somewhat greater than for 1901. Alcoholism also counts for an increase in admissions. The detailed figures are: Gonorrhea, 771; syphilis, 606; chancre, 284; alcoholism, 248. The total admissions for injuries of various character were 2,940, being divided among wounds, 942; contusions, 706; sprains, 612; fractures, 242; hernia, 175; burns, 171; luxations, 65; drowning, 27. The admissions for pulmonary diseases show a decrease from 1901, there being 158 admissions for pneumonia in 1902 to 185 for 1901, and 130 for pulmonary tuberculosis in 1902 to 125 in 1901. The average for organic diseases shows a decided increase; 190 admissions for heart disease during the year to 105 during 1901, and 46 admissions for nephritis to 25 for 1901. Diarrheal affections and dysentery are still prevalent, as is typhoid fever to a less degree, the admissions being: Diarrheal affections, 783; dysentery, 176; typhoid fever, 125; the total of these, 1,084, being an increase of 135 over the admissions for 1901. Among admissions for causes of an unusual nature are to be noted cholera (Asiatic), 11 cases, with 6 deaths; and starvation, 42 cases, with 12 deaths; all occurred in the Philippine Islands. Upon comparing these returns with those of the previous year it appears that there has been a decided increase in the number of cases treated for malarial affections, mumps, and measles; while the other diseases prevalent in the service remain at about the same average when compared with the total strength of the force employed. The small actual increase in figures can well be attributed to the increase in the complement of the Navy and Marine Corps during the year.

EASTERN STATES.

McLean Hospital Changes.—Dr. Edward Cowles will soon retire as superintendent of the McLean Hospital at Waverly, Mass., a position he has held since 1879 when the institution was known as the McLean Asylum. The trustees of the Massachusetts General Hospital have passed commendatory resolutions on the work of Dr. Cowles and appointed him a member of the board of consulting physicians for the McLean Hospital, a board just created. The new superintendent at McLean will be Dr. E. Stanley Abbott, at present assistant superintendent of the Boston City Hospital.

NEW YORK.

Columbia University.—The winter course of lectures before the Newman was opened December 15 by Dr. J. J. Morrisey of New York who chose for his subject "University Education and Citizenship."

Cornell University Medical College.—Dr. Alexander, professor of genitourinary diseases, has obtained a leave of absence on account of illness and this year the lectures upon the surgery of the genitourinary tract will be given by Dr. Charles L. Gibson.

Antidrug Movement at an End.—Annoyed at the manner in which they have been connected in newspaper stories with a private medical enterprise, the International Committee organized for the suppression of the drug addiction has dissolved, with a declaration that not one member had profited to the extent of a single cent through his connection with the work. It was also stated in the preamble of the resolution that contributions, despite many public appeals, have not been sufficient to carry on the benevolent part of the work on an extended scale.

Deathrate of Tuberculosis in New York City.—There is published in *Charities* for December 12, 1903, a table giving the deathrate, number of deaths, and other data concerning pulmonary tuberculosis in the city of New York from 1887 to 1902. This table shows that in 1887 the deathrate from that disease was 4.27 per 1,000 of population. In 1902 the rate was 2.29 per 1,000. In Greater New York the rate in 1898 was 2.25 per 1,000; in 1902, 2.08. The table also gives the number of cases reported yearly since registration was begun, number of specimens of sputum examined, and the deathrate from all forms of tuberculosis.

The Eastern Medical Society of New York has engaged permanent quarters at Clinton Hall, 151-153 Clinton street, New York. Possession will be taken on or about January 1. The building will offer every facility of the modern club house, all of which will be open to the members. A reference library is one of the projected features of the society. At the annual elections held recently, the following officers were chosen: President, Dr. Louis J. Ladinski; first vice-president, Dr. David Robinson; second vice-president, Dr. Tobias Borger; treasurer, Dr. Joseph Barsky; corresponding secretary, Dr. Abr. L. Wolbarst; recording secretary, Dr. A. J. Ronginsky; trustee, for 3 years, Dr. Wolf Freudenthal.

The Herter Lectures at Bellevue.—The Faculty of the University and Bellevue Hospital Medical College announce the first series of Christian A. Herter lectures to be delivered by W. D. Halliburton, M.D., F.R.S., Professor of Physiology, Kings College, London, on "The Biochemistry of Nerve and Muscle." These lectures will be an extension of a course delivered before the students of the University of London; they will be illustrated by experiments and will contain the results of the lecturer's own physiologic and pathologic research. The course will begin on Monday, January 4 and will continue until Saturday, January 16, daily at 4 o'clock, at the Carnegie Laboratory, 338 East 26th street. Those desiring reserved seats for the course will please communicate with Dr. E. K. Dunham or Dr. Graham Lusk.

Serum for Typhoid Fever.—News from New York under date of December 17 says: Remarkable cures of typhoid fever patients are reported by Beth Israel Hospital, where a serum imported from Italy and Switzerland is being used. Although the remedy has been in use more than 3 months, it has just been made public. In that time 30 cases have been treated at the hospital, which is in the most crowded quarter of the East Side. Not one of the patients died, and in some instances improvement set in before the fever had run more than half its regular course. The improvement was invariably permanent, and many patients were dismissed from the hospital from two to three weeks before the usual time. A small quantity of the lymph is injected into the body 3 times a day, sometimes in the thigh, sometimes in the breast. The operation is of the simplest and practically painless. The injections are in addition to the regular treatment for reducing the temperature, careful diet and nursing. Physicians in charge of the institution refuse to discuss the matter fully, pending the preparation of a detailed report on each case for the use of the medical profession. They admit the successful use of the new serum, but maintain that the treatment is still in its experimental stage.

PHILADELPHIA, PENNSYLVANIA, ETC.

To Vaccinate Railway Men.—The Pennsylvania Railroad Company has issued orders, compelling all employes to be vaccinated.

Contagious Diseases in Allegheny.—The following cases of contagious diseases were reported to the Allegheny Bureau of Health for the week ended December 12: Smallpox, 22 cases; diphtheria, 27 cases; scarlet fever, 7 cases; typhoid fever, 12 cases.

Contagious Diseases in Pittsburg.—The following cases of contagious diseases were reported to the Pittsburg Bureau of Health for the week ended December 5: Smallpox, 27 cases; diphtheria, 27 cases; scarlet fever, 19 cases; typhoid fever, 88 cases. This is an increase of 13 cases over the number reported for the preceding week.

Vaccinating in Allegheny.—The vaccinating corps of the Allegheny Bureau of Health recently vaccinated over 1,200 persons in the districts where most of the unvaccinated of the city reside. It is believed that the hardest part of the work is now accomplished and that Allegheny is prepared to efficiently cope with any further outbreak of smallpox.

Fatal Injury of Insane Patient.—Two attendants in the insane hospital of the Allegheny County Home at Woodville, near Pittsburg, are charged with the murder of an inmate. Ordinarily the man was not of a dangerous type, but had on several occasions injured other inmates during epileptic seizures. Recently while walking about the ward he was seized with an epileptic fit. He was caught by the attendants, and in the struggle that followed was thrown to the floor, dying about 15 minutes later. Postmortem revealed a broken rib, which had penetrated the heart and caused death.

SOUTHERN STATES.

Herter Lectureship.—The first lectures in the memorial lectureship endowed by Dr. and Mrs. C. A. Herter will be delivered at the Johns Hopkins University, Baltimore, Md., by Professor Paul Ehrlich, of Germany. The date has not been determined, but will probably be some time during April. It is stated that the lectures will be in German, but English translations will be distributed to the audience. They will, it is supposed, deal with the problems of immunity.

WESTERN STATES.

Utah has Ordained a Feast of Disinfection.—According to *Il Politecnico*, Rome, November 21, 1903, Utah, "one of the United States," has set apart the first Monday of each October for a general disinfection of public meeting-places, attaching a penalty for failure to comply. To this day is given the name of "Feast of Disinfection." More recently the "Feast" seems to be applied to some of Utah's public men as well as public places.

Sanitary Power of the Press.—In a recent bulletin of the Chicago Health Department, Commissioner Reynolds states that the press of that city is their chief sanitary pulpit. One prominent daily had put in type ready for instant use a warning from the Department bulletin regarding the danger to children of unboiled drinking-water if the snow should rapidly melt and flush the sewers into the lake. This notice at the proper time appeared in several places in its columns. The commissioner says: "The agency of the press as a sanitary pulpit multiplies the effectiveness of the Department's efforts ten thousand fold."

Mortality of Michigan during November, 1903.—There were 2,623 deaths reported to the Secretary of State for the month of November, or 1 death less than the number for the preceding month. The deathrate was 12.9 per 1,000 population. By ages, there were 412 deaths of infants under 1 year; 171 deaths of children aged 1 to 4 years, inclusive, and 789 deaths of elderly persons over 65 years of age. Important causes of death were as follows: Pulmonary tuberculosis, 158; other forms of tuberculosis, 27; typhoid fever, 80; diphtheria and croup, 112; scarlet fever, 14; measles, 7; whoopingcough, 28; pneumonia, 206; cancer, 140; accidents and violence, 194. The number of deaths reported from typhoid fever was less than during October. Tuberculosis also showed a decrease, while diphtheria, scarlet fever, and other diseases of children showed a considerable increase. There were no deaths from smallpox during the month. One death from chickenpox was reported from Ashland township, Newaygo county.

Disease and Death in Indiana in November.—The monthly statistics of the State Board of Health show that bronchitis was the most prevalent disease in November and tonsillitis was the next prevalent. Pneumonia was more prevalent than in the same month last year, the deaths being 241 and 181, respectively. The total number of deaths reported was 2,518, an annual rate of 12.2. In the corresponding month last year 2,406 deaths were reported, which is a rate of 11.6. By important ages the deaths were: Under 1 year, 322; 1-5, 175; 5-10, 98; 10-15, 54; 15-20, 83; 65 and over, 666. Some important causes of death were as follows: Pulmonary tuberculosis, 279; other forms of tuberculosis, 38; typhoid fever, 105; diphtheria, 68; scarlet fever, 18; measles, 6; whoopingcough, 6; pneumonia, 241; diarrheal diseases, 35; cerebrospinal meningitis, 20; influenza, 11; puerperal septicemia, 11; cancer, 94; violence, 163; and smallpox, 1. The city deathrate during the month was 15.5, which is 3.3 higher than the State rate for the same month. In the corresponding month last year the rate was practically the same as this year. The country deathrate is 10.4. In the corresponding month last year it was 9.7. **Smallpox:** Three hundred and twenty-four cases of smallpox with 1 death in 33 counties occurred in November. It is a singular coincidence that exactly the same number of cases was reported in October and also the same number of deaths. In the corresponding month last year there were 441 cases with 2 deaths, and 40 counties were invaded. **Tuberculosis:** The tuberculosis deaths numbered 279, a rate of 135.2 per 100,000. The same month last year the deaths numbered exactly the same, which is another remarkable coincidence to be noted. Of the total deaths from pulmonary tuberculosis, 146 were females and 133 males. Twenty-eight of the males were married and between the ages of 18 and 40, and they left 56 children under the age of 12. Sixty of the females were married and between the ages of 18 and 40, and left 120 children under the age of 12. The disease, therefore, made in November 56 fatherless orphans and 120 motherless orphans. **Typhoid fever:** Typhoid fever caused 105 deaths. The deathrate from this cause for the whole State was 50.9 per 100,000. The city rate was 44.7; country rate, 54.4. **Pneumonia:** Pneumonia deaths numbered 241, a rate of 116.8 per 100,000. In the corresponding month last year the rate was 87.7. The disease prevailed very much more extensively in the cities than in the country, the rates being, respectively, city, 179.1 per 100,000; country, 84.5. Pneumonia does not lead pulmonary tuberculosis as a cause of death in Indiana, and has only done so in 1 or 2 months in the last 4 years. **Violence:** The violence deaths numbered 163, rate of 79. Of the violent deaths, 4 were murders,

27 suicides, and the rest accidents. Nine of the suicides were females, and chose the following methods of self-destruction: Drowning, 1; morphin, 3; carbolic acid, 3; other poisons, 2. Some of the causes of accidental deaths were: Railroads 23, 2 of them being females; burns and scalds 27, 16 being females; fracture of skull 11, all males; fracture of femur or other bones 11, 7 being females; accidents in mines, 3; electricity, 1; horses, 3; explosions, 2.

FOREIGN NEWS AND NOTES

GREAT BRITAIN.

Honor for Physician.—The King of Italy has, through the Italian Ambassador, conferred the decoration of Cavalier of the Order of the Crown of Italy on Dr. James Donelan, attached to the new Italian Hospital in London, in recognition of his services in establishing the throat department.

OBITUARIES.

Clifford Doyle Boal, at his home in Baden, aged 24. He was the son of one of the best known physicians of Beaver county. He received his medical education at West Penn Medical College, and in California, where he resided for two years while under treatment for tuberculosis.

Hugh Burford, at his home in Brunswick, Ga. A graduate of the Savannah Medical College. He was acting assistant surgeon in the U. S. Public Health and Marine-Hospital Service. He was one of the founders of *American Medicine*.

William H. Webb, at his home in Philadelphia, December 23. A graduate of Jefferson Medical College, in 1866. He served during the Civil war as laboratory assistant at Washington, and afterward on the field.

E. L. Carr, of Pittsfield, N. H., December 22, as result of injury by a train, aged 62. For several years he was State superintendent of schools.

Timothy O'Connor, in Denver, December 11, aged 45. A graduate of the College of Medicine and Surgery of the University of Minnesota.

James L. Patty was found dead in his buggy near Brooksville, Miss., December 12. A graduate of the Louisville Medical College.

Charles H. Bushong, in New York City, December 21, aged 47. A graduate of the College of Physicians and Surgeons, New York.

Edward F. C. Rembe, in Lincoln, Ill., December 14, aged 49. A graduate of the St. Louis College of Physicians and Surgeons.

Josiah W. Willis, in Galesburg, Ill., December 14, aged 68. He was a graduate of the Hahnemann Medical College of Missouri.

A. L. Kline, at his home in West Enterprise, Miss., December 12, aged 57. A graduate of the Louisville Medical College.

Wilfred Stedman Fisher, at his home in Ann Arbor, November 30, aged 26. A graduate of the University of Michigan.

Daniel Embury Kissam, at Huntingdon Harbor, December 24, aged 87. He served as surgeon during the Civil war.

George Horace Brown, at Gilmanton, N. H., December 5, aged 50. A graduate of the University of Vermont.

Elisha Hall Bridges, at Ogdensburg, N. Y., October 9, aged 62. A graduate of Bellevue Hospital Medical College.

Samuel M. C. Hawthorne, at Pine Apple, Ala., December 9; a graduate of the Medical College of Alabama.

Albert Moser, at Lima, Ohio, December 9, aged 38. A graduate of Harvard University, Medical Department.

George Horine, at Americus, Ga., December 8, aged 47. A graduate of the Kentucky School of Medicine.

Charles B. Ridley, at LaGrange, Ga., December 14. A graduate of the New Orleans School of Medicine.

Alfred H. Brundage, at Xenia, Ohio, December 10, aged 68. A graduate of Albany Medical College.

Alvinzi G. Thomas, at Atlanta, Ga., December 14, aged 70; a graduate of the Toledo Medical College.

Fred J. Rothacher, at Detroit, December 8, aged 36; a graduate of the Detroit College of Medicine.

George A. Hollister, at Bellevue, Ohio, December 9. A graduate of the Ohio Medical University.

N. B. Ridgway, at Gallon, Ohio, December 12; a graduate of the Starling Medical College.

Otto Fuls, in Cincinnati, December 10; a graduate of the Miami Medical College.

Henry James Ward, at Birmingham, Ala., December 16, aged 61.

John Tallaferra Jones, at Charlotte, Va., December 10, aged 78.

Wilbur F. Harding, at Westfield, Mass., December 24, aged 68.

Carlton D. Ashley, at Cleveland, Ohio, December 9, aged 81.

Lincoln C. Sappington, at St. Louis, December 14, aged 46.

T. M. Gwin, at Blacksburg, S. C., December 9, aged 64.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

REPORT OF THE MATERNITY HOSPITAL OF THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA FROM JANUARY, 1888, TO MAY, 1903.

BY

MARY W. GRISCOM, M.D.,
of Philadelphia.

Formerly Associate in Obstetrics at the Woman's Medical College of Pennsylvania. Now Senior Obstetrician at the Woman's Hospital, and Attending Physician to the West Philadelphia Hospital for Women.

After reading an article in *American Medicine* for April 11, headed, "The Possibilities of Clean Obstetric Work in the Slums," it seemed of interest to report 15 years' work by woman medical students among the poorest of Philadelphia's poor.

In January, 1888, Dr. Anna E. Broomall established an out-practice maternity hospital in order that the students of the senior class might have practical experience in obstetrics.

At first only one case could be supplied for each student, but for several years every student has delivered 8 patients before her graduation.

The students were resident at the hospital during attendance on their patients and measured the pelvis of all applicants, made daily visits to the patients under their care and kept a careful record of the labor and puerperium.

The students' bags were supplied with the usual obstetric armamentarium, excepting forceps and ether. Basins for solutions were added and sterilized cloths in packages for the navel, and for the vulva in case of stitches; but no perineal pads were possible.

The personal antisepsis was first mechanical, followed by potassium permanganate and oxalic acid, then mercuric chlorid solution, 1-1,000.

After a rectal injection the patient was cleansed with soap and hot water, and mercuric chlorid solution. No douches have been used for several years.

External examinations and frequent auscultations were encouraged. One internal examination was allowed after the preparation of the patient and one after the rupture of the membranes. An interne went with the student to every primipara and was sent for in every case of complication. Primary repairs were made in all cases, mostly by the students.

During the winter of 1901-1902 many women were attended as they came off shipboard. One woman was delivered of twins within 24 hours of her arrival in this country. And frequently in these cases labor was ineffectual until nourishment had been supplied by the District Charity Organization. Often one dishpan was the only basin the house afforded and it was used in rapid succession for all purposes of sick-room and culinary department (hence the basins in the obstetric bag).

Occasionally the trained nurses from the Visiting Nurse Society made daily visits, but unless there was some complication they did not care for the work, and the students were interested in any complication, so trained nurse assistance was rare.

The proportion of contracted and deformed pelvis was large and many serious forceps deliveries were made amid the poorest and dirtiest surroundings. One woman who did not send till labor was far progressed was found with the fetal head in the rectum, owing to a cicatricial contraction of the vagina due to sepsis after her previous labor. This band was cut to save the remnant of a sphincter ani, and the child delivered, but the whole rectovaginal septum was ruptured. She was sent to a hospital and made an uninterrupted recovery.

One great difficulty met in the work was the superstitious refusal on the part of patients to acknowledge any previous dystocia, and when it had existed, even if it was acknowledged, to get them to send early. They seemed to hope that by waiting all would end well.

Certain women became well known to the doctors in

charge. Some who had had difficult labors learned at last to notify the hospital early and submitted to the induction of premature labor if necessary, others remained firm in their belief in nature. One little rachitic dwarf of 54 inches, with an external anteroposterior measurement of 16 cm. lost 2 babies through not sending till she had been in labor many hours. One child had to be delivered by craniotomy; the second, a transverse presentation, after version.

A deaf mute illegitimately pregnant, waited 17 hours after the rupture of the membranes, in active labor, and when found the child was dead—a neglected transverse presentation. Decapitation was easily accomplished. Her second labor began the same way but she sent early and after version a living child was delivered. Tight lacing accounted for the presentations, as her pelvis was normal.

During the 15 years and 4 months ended May 1, 1903, when Dr. Anna E. Broomall resigned from the chair of obstetrics, in the Woman's Medical College, and the work passed to other hands, 3,156 patients were attended with 2 maternal deaths. The last death in April, 1897, was due to gonorrheal peritonitis. The woman had been in labor many hours before the arrival of the hospital doctors, and had a high temperature and rapid pulse. The head was on the perineum and fetal heart poor. Forceps were applied and the child delivered. The woman died on the ninth day of peritonitis—no autopsy was allowed but her symptoms and a gonorrheal ophthalmia in the child made the diagnosis clear. She was the third instrumental case for the day; the first, a craniotomy and the second, axis-traction forceps; both did well.

The other death was of a woman who applied for medical help and food after she had been on a drunken spree for a week. The child was presenting by the brow and ether had to be given to correct the presentation. The woman suddenly collapsed and died undelivered.

A woman, an unregistered case, sent for assistance in labor. She was found with a double pneumonia and after a quick delivery was sent to a general hospital. She died 2 weeks later from some heart complication, but as her death did not occur till after the 14 days during which the students attended their cases, and as the short labor was only an incident in the acute disease she was never included in the obstetric mortality.

I have enlarged sufficiently to show that all varieties of abnormal conditions among Russians, Poles, Italians, negroes and poor Americans were met and combated under the most adverse circumstances, and the mortality was .06 of 1%; smaller than any I have seen reported.

CONDEMNATION OF DR. MANSON'S "NEW WAY OF TREATING TUBERCULOSIS."

BY

M. L. STEVENS, M.D.,
of Asheville, N. C.

In the issue of *American Medicine* for November 21 there appeared an article setting forth "A New Way of Treating Tuberculosis." The following comments anent it might be construed as a reflection upon the wellknown intelligence of the readers of *American Medicine*, all of whom I hope are able to see the folly and danger of the plan therein set forth. But if there is one among us so ignorant of the principles underlying the immunizing treatment of infectious diseases with anti-toxins, serums and laboratory extracts of the pathogenic bacteria of these diseases, and with attenuated cultures of these same bacteria—so reckless of the life of those unfortunates entrusted to his care as to inject into their bodies the sputum from tuberculous patients, there may be others, who reading his statement that, "it acted miraculously and restored to health," would be foolishly enough to repeat (if it be a repetition) the experiments. Considerable careful work has been done by scientific men in demonstrating the feasibility of producing immunity to tuberculosis in animals by injecting them with attenuated cultures of tubercle bacilli. But with the practicability of this shown, none of them have had the temerity to inject even a greatly attenuated culture into a fellow man.

And that physician is guilty of more than malpractice who in the present state of our knowledge on this subject, injects into his patient virulent tubercle bacilli such as are present in tuberculous sputum, to say nothing of the constant presence in such sputum of various associated bacteria (diplococci, staphylococci, streptococci, etc.) which in animal experiments are so often productive of fatal sputum septicemia. It is indeed not strange that a slightly turbid solution of this sputum "produced increased temperature and rapid dissolution." It is such articles and such work as this that foster the ill-founded prejudice against properly applied immunizing treatments. If the doctor purposes continuing in the use of this "new treatment" it is hoped that he will, in the interest of his patients, first try it on himself. If he does, and does it thoroughly, his patients will escape the untimely death to which such treatment would expose them.

THE ARMY CANTEN.

BY

EVAN O'NEILL KANE, M.D.,

of Kane, Pa.

To the Editor of *American Medicine*:—A long article filled with statistics, entitled "The Canteen," appears in your journal of December 5. It, like its voluminous statistics, seems characterized by the bias of a preconceived opinion in favor of beer drinking in barracks. Even in its first lines it scores Congress for "curtailing the operation of the army canteen." In other words, for endeavoring to suppress drunkenness in the army. In my opinion, Congress knew what it was about. Every practical physician and every student of human nature knows that vicious habits are formed and grow through an immoral environment and the lack of restraint, moral and physical. If, therefore, we would really wish to do away with drunkenness in the army we must alter the environment and impose effective measures against vicious conduct. If men drink whisky and rum outside the barracks, when they cannot get beer and wine inside of the canteen bar-room (where many have learned the drink habit), then the speakeasies and saloons outside the barracks should be broken up and the men who drink in them peremptorily and suitably dealt with. Thus, those who have not yet formed habits of intemperance, will have no motive nor opportunity for acquiring them. Those who have already acquired a taste, and yet not an ungovernable appetite (as is the case of men, under-officers as well as privates), can without difficulty alter their mode of life, for beside finding the tone of those of higher rank opposed to drinking, liquor being unobtainable the taste will vanish, while the third class, those enthralled wretches who are bound soul and body by the chain of debauchery, must sober up or die and relieve the organization and society of a loathsome and dangerous incubus.

A firm hand and a sober head and an unflinching determination to enforce law and order on the part of the officers and the removal of temptation from under the noses of the men is, in fact, all that is necessary to solve the liquor problem in the army and to insure decency and sobriety.

The feeble argument is urged by the opponents of temperance and the promoters of the canteen bar, that, if liquor is not sold within the post the men will drink unrestrainedly outside. And they admit that with or without the canteen bar-room, drunkenness is of common occurrence.

A little investigation divulges the fact that liquor is commonly found upon officers' tables, even though with them spree-drinking and boozing are usually frowned upon and concealed. If this is the fact, as is shown by statistics, the organization itself supported and perpetuated by us for the protection of society against foes within as well as without, for the enforcement of law and order, cannot restrain its weaker members from drinking and suppress the saloons and brothels outside the barracks within a few miles' limit, what, in the name of public decency, can it do, and what kind of moral tone and backbone have the officers? Every large railroad company recognizes the necessity of sobriety among its employes for the protection of its property and the lives of the public. On

western roads they now have the system of spying with concealed kodaks for taking snapshots of employes found drinking at bars when off duty, and all such employes are severely dealt with. Are lives and property less endangered by a drinking army?

What is the matter with our army officers and their discipline that the only way to prevent men from drinking whisky outside is to furnish them with beer inside? Are they off-leave, lobbying in Washington, or like the men—or a booze? If this is the way our army is conducted, we had better have no standing army, for it will only serve as a means of propagating drunkenness and venereal disease, and will betray us at a pinch like the army of Belshazzar in the hour of need. If our standing army is to degenerate to the level of those in old Europe, with soldiers debauched to a level below the brute, we need not be surprised to find the same degraded tone among the officers, and have enacted again scenes like that of the famous charge of the Light Brigade, where by the blunder of one drunken officer, an army of brave men was sacrificed.

Truly we need not wonder that in the Philippines since our army has taken possession there is an immeasurably larger amount of drinking than before our occupancy. And we exclaim, to quote Hamlet, "Something is rotten in the State of Denmark."

[The reform of the officers themselves, and the breaking up of the speakeasies and saloons outside the barracks are certainly desirable, but the first must be done morally and the second legally. A thoroughgoing attempt may succeed if persistently carried out for several centuries. In the meantime, and in the absence of the best, would it not be well to have the better? The columns of *American Medicine* cannot be spared to continue this controversy.—Editor *American Medicine*.]

MEDICAL TREATMENT SOUGHT BY EDDYITES.

BY

HOWARD CRUTCHER, M.D.,

of Chicago.

To the Editor of *American Medicine*:—The following report is based on personal knowledge:

A young woman of 18, accompanied by her mother, was down town on a shopping tour. About 11.30 in the forenoon mother and daughter entered one of the private rooms of — where the mother applied to the daughter's eyes some drops of a solution prescribed by a regular oculist. They then repaired to another place, took seats at a table, and gave orders for a luncheon. At this point the daughter remembered that she had been directed to take some internal medicine, whereupon she drew from her pocket a vial, concealed in a handkerchief, and swallowed about an ounce of a watery solution, which was almost instantly found to be the wrong vial from the one she intended to empty, and which contained about .26 gm. (4 gr.) of atropin. Both hurried at once to a drug store, thence to the office of a physician. About 20 minutes elapsed from the time the poison was swallowed until they rushed into the office of the physician. The doctor immediately began energetic treatment, in which he was assisted by some colleagues. The mother went to the telephone and calling up "a reader" (eddyite) requested a "treatment" for her daughter. After the notification of "the reader," members of the patient's family were advised of her condition. After 14 hours' active office and hospital treatment on the part of the physicians the girl was convalescent. She recovered fully.

The next day but one the mother coolly informed the medical attendants that the happy and really unexpected recovery was due to the services of "the reader," who was at no time nearer than 5 miles to the scene of action.

Several things about this case puzzle me. The young woman is an epileptic. She is under the care of a physician and also of an eye specialist. The application of eyedrops by the mother, the rush to a drug store, the hurried call upon a physician, the removal to a hospital, and the free consent to the application of recognized antidotal measures are assuredly more than puzzling. If the substantial details of this case were not well known to several reputable physicians I should hesitate to report it; but it is literally true in all essential details. Borrowing a familiar phrase, comment would appear unnecessary.

ORIGINAL ARTICLES

THE EARLY DIAGNOSIS OF ARTERIOSCLEROSIS.¹

BY

ALFRED STENGEL, M.D.,
of Philadelphia.Professor of Clinical Medicine, University of Pennsylvania; Physician
to the Pennsylvania Hospital.

In the processes of involution that occur with advancing years, the primary, and by far the most widespread and important, is the loss of elasticity of the bloodvessels and their hardening. Following this, there is a train of pathologic consequences, any one or any group of which may become conspicuous and dominate the remaining years of life. All the research of physiologists and pathologists has not thus far thrown any definite light on the particular causes which operate to bring about the vascular changes of physiologic senility, but considerable light has been thrown on the factors that are concerned in the premature development of this condition, and there is more than a little evidence to indicate that an early recognition of the development of this condition and a proper regulation of the life and habits of the individual may defer the more advanced stages of the trouble, if indeed they cannot cause a restitution of previous conditions.

Arteriosclerosis may be a localized or a diffuse process. The form that I have in mind is that which approaches the normal or senile type of change. In this the pathologic alterations are found primarily in the smaller bloodvessels, while the lesions of the larger vessels are of comparative unimportance so far at least as the symptomatology and the progress of the condition are concerned.

Von Basch, who has written much on this subject, suggests the term *angiosclerosis* to indicate the alterations in the vascular system as a whole, and particularly the changes in the smaller vessels, and uses the term *arteriosclerosis* as of more restricted applicability. It is quite conceivable, as he maintains, that areas of sclerotic change might occur in the aorta or any other large vessel without influencing the health of the individual very greatly, provided of course the smaller vessels remained in their normal condition. As a matter of fact such a state of affairs does not occur, and when marked arteriosclerosis of the larger vessels is present, the smaller vessels and capillaries have long been affected. From the point of view of diagnosis, therefore, it is important to recognize the involvement of the smaller vessels and not that of the main trunks. Arteriosclerosis in its fully developed stage can be recognized with no great difficulty in most instances, but a positive determination of the existence of the earlier stages is extremely difficult, but most essential if we are to accomplish anything in the way of controlling the progress of the disease. In a strictly pathologic sense I do not believe that von Basch's views regarding the prior onset in the smaller vessels is often justified. With rare exceptions I believe that arteriosclerosis is indeed a general disease as Gull and Sutton claim, and that while slight changes in the smaller vessels are capable of producing serious consequences, and similarly slight alterations in the larger vessels are of comparatively little significance, both the large and the small vessels are as a matter of fact involved simultaneously or nearly so.

From the diagnostic point of view, it is important then to consider involvement of the smaller vessels first, but from the broader pathologic aspect, all evidence would indicate that the disease is more or less uniformly distributed. In the subsequent stages, the changes in the large vessels may increase rapidly, while

those in the smaller vessels remain practically stationary, or the reverse may occur. These peculiarities of subsequent progress may account for the differences in individual cases in the clinical course and in the duration of life. There can be no doubt of the unequal progress of events when the multifarious character of the symptomatic manifestations is recalled. In the later stages, one case presents itself in the aspect of a cerebral disease, another in the form of a cardiac malady, while in others the kidneys seem essentially vulnerable.

The causes that lead to arteriosclerosis may be very briefly discussed, since their recognition has now become practically established. If in a theoretic spirit, we assume that senile changes develop after the wear and tear of life have exhausted the vital forces and the capacity of the tissues to rejuvenate themselves, it might be thought that any habits or conditions of life which increase the stress and strain would lead to a more rapid development of senile changes. As a matter of fact, experience bears out this assumption, and from some slight review of such statistical evidence as is available in the Census Reports of the United States, I was led to believe that cardiovascular diseases have become more common in this country in the last 5 decades, and the opinion of physicians of experience is almost uniformly consonant with this view.¹ It would be difficult to analyze the various features in modern life that contribute toward this result, but one can readily appreciate how the excessive activity resulting from rapid transportation, the use of the telegraph, telephone, and other modern inventions, may play a part. So far as this country is concerned, and to a less extent, in other countries, the complex relations of social and business affairs also play a part.

The result of nervous strain on the vascular system is twofold. Continued anxiety or exhausting mental exercise has undoubtedly much to do with the development of arterial sclerosis, and sudden shocks or emotional stress in many cases seem to be the determining cause of increased activity in the arterial disease, or of rapid failure of the heart and other organs to compensate the vascular condition.

I cannot forbear expressing in this place my conviction that infectious diseases occasion the development of changes in the arterial system that subsequently, under the operation of other causes, become pronounced. Thus the immediate results of a severe attack of typhoid fever may be a disturbance of the heart and bloodvessels that suggests a serious pathologic condition. In the course of time, however, the cardiovascular system seems to recover entirely, and not until some years have elapsed and until other causes have become operative are the evidences of extensive vascular disease evident. I believe that such infectious diseases lay the foundation for the ready development of arteriosclerosis in later years, just as excessive exercise may occasion changes in the heart muscle that during the period of robust manhood are of little consequence, but later increase in degree and seriousness.² I appreciate that much of this must be regarded as theoretic, though practical experience warrants the suggestion, and would justify a careful investigation.

Among the more definite and direct causes are: Laborious work, overuse of alcohol, overfeeding, chronic metallic poisoning, notably lead-poisoning, and some infectious diseases, particularly syphilis. One of these causes deserves particular mention, because it is less frequently considered, and yet in the opinion of many well-qualified physicians, a cause of great importance—I refer to overfeeding. I have myself seen advanced arteriosclerosis in persons who had lived the most correct lives in every respect, excepting this. It could not, of course, be assumed from one case or a few cases that

¹ Read before the Lyncoming County Medical Society, November 13, 1903.

² University Medical Magazine, October and November, 1900.

³ See "The Immediate and Remote Effects of Athletics on the Heart Muscle," American Journal of the Medical Sciences, November, 1899.

this is the operative cause, but accumulative experience is strikingly significant in this direction.

Heredity must not be lost sight of. It is a well-known fact that in certain families diseases which are the result of arteriosclerosis are not infrequently found in one after another generation. Osler speaks of this in the sense that the primary material of which the arterial system is made is of low order, and that its elasticity is soon exhausted. We cannot do any more than speculate on the probable truth of such an hypothesis, but the record of arterial disease in various members of the same family is more than a coincidence, or the result of the operation of the same causes acting in the common environment.

The results of arteriosclerosis are varied as I have said. In the normal and typical senile form there is a gradual failure of organic functions, resulting from inadequate circulation in the important organs. Unless special causes operate to promote the disease in one and retard it in another part, the progress is an orderly and a uniform one, and at last the individual is sans teeth, sans eyes, sans taste, sans everything. In pathologic or premature arteriosclerosis, the causes which have brought about the premature development of the disease also tend to make its progress in one part more rapid than in another, and we find, therefore, that when manifest clinical symptoms develop, the brain, heart or the kidney suffers disproportionately. It is true that in the normal senile change the symptoms may be at last unequally marked in one or another direction, but on the whole, the progress is more or less uniform. In fully developed arteriosclerosis, when the earlier stages have been obscure, the patient may present himself to the physician with symptoms pointing exclusively to one or another organ, though as a rule a careful study of the patient will reveal the underlying vascular cause. It is at this stage that we are usually able to recognize the disease. Unfortunately, the beginnings are obscure and the attempt has not been made with special energy to determine the earlier phenomena. The last few years, however, have witnessed a great improvement in methods of clinical investigation of the cardiovascular apparatus, and I believe the time is now ripe for an active campaign of exploration in this field. I am convinced that the disease could be recognized earlier if the profession were alive to the necessity of determining the very earliest symptoms, and it is not too much to hope that the progress of the disease can be retarded if not completely arrested.

We have learned how very important is the early recognition of tuberculosis, and the timely climatic, dietetic, and medicinal treatment have saved thousands who would inevitably have gone to destruction. The same thing in a lesser degree may be true of this immensely more frequent malady, for it can be said that while the German clinician's dictum that every one has some time or other a little tuberculosis is true, it is still more true that every one who has not been cut off prematurely by some other ailment must come to his end through arteriosclerosis directly or indirectly. The necessity of early recognition stands upon exactly the same ground in this disease as in tuberculosis. If the process has advanced to complete destruction of the tissues affected, the time has gone by when any remedial measures can possibly avail.

Before I turn to the clinical side, let me say a few more words regarding the pathology of the condition. When slight sclerotic changes develop in the small bloodvessels it is easy to see that no material or demonstrable alteration might be discoverable in the general conditions of the circulation, while the diminished supply of blood in important organs might readily occasion derangements of their function, and the widespread though slight impediment to circulation might affect the heart's action injuriously. As a matter of fact, my experience leads me to look in these directions for the earliest evidences of the developing disease, and in

reviewing my early knowledge of cases of arteriosclerosis that eventually terminated with pronounced evidences of the disease, I see how the oncoming of the disease was foreshadowed, or in its early stages, at least vaguely indicated. The solution of the early diagnosis of this disease is the business of the pure clinician. I believe that the pathologist can help us but little. A retrospective investigation of every case that has been under the careful observation of the physician will throw more light on the early indications than the most painstaking pathologic study of dead tissues. The pathologist and physiologist have shown us how and where to direct our attention in this study; the solution is the affair of the physician.

The first effect of loss of elasticity of the bloodvessels must be an impediment to the easy circulation of the blood, an increase in the work of the heart, and a consequent increase of blood-pressure. If the normal blood-pressure were a fixed amount, and if there were no causes of frequent or even habitual increase of peripheral vascular tension, the recognition of this early stage might be easy; but we know that in its infinitely complex system of compensations the circulation is adapted to varying conditions at the periphery or center, and in the very first stages of arteriosclerosis the blood-pressure may be possibly lowered instead of raised by the relaxation of the diseased vessels, either as a result of the direct weakening of their walls or of the action of vasodilator mechanisms. Such a preliminary lowering of blood-pressure is probably quite temporary and rather occasional than constant during the brief term of its existence. Soon the pressure becomes increased and remains so with only occasional depressions. In the late stages of the disease, heart weakness from myocardial degeneration may become pronounced and a durable and serious reduction of pressure may develop. This, however, is a final phase, in which we have no special interest to-day. It may be said, then, that elevation of blood-pressure is an early condition of arteriosclerosis, and in the review of every case that I have been able to study from the beginning this has been an invariable symptom. The means of determining this is the study of the pulse by the finger, the character of the first heart-sound at the apex and the second sound at the aortic area, the sphygmogram, and the results obtained with some instrument for recording arterial pressure. I need not review the features that indicate increased arterial tension to the palpating finger. These are well known to all of us. The character of the first heart-sound is, however, less commonly appreciated. The increased difficulties of the circulation cause an early lengthening and an increased heaviness from augmented muscular action of this sound, and these characters are often sufficiently clear to be readily appreciated by a trained ear. Later the peculiarities of this sound become more manifest, and finally, when the myocardium becomes weakened by disease and its unequal effort, the sound loses muscular tone, becomes vibrating and uncertain, and at last may be attended with or replaced by a murmur.

The second heart-sound is accented early and remains so almost constantly, even to the very latest stages. This is too well known to require further discussion.

The sphygmogram shows a tendency to increase of what is called the tidal wave. The characteristic curve with sloping ascent and delayed decline is significant of late stages of the disease; it is a development of a much later period than that which I believe we should recognize. Even from the first, however, the percussion wave of the sphygmogram is often less sharp and pronounced than in a normal curve, the reason for this being, in my judgment, the more prolonged expressive action of the left ventricle occasioned in arteriosclerosis as it is in aortic stenosis by the *resistentia a fronte*.

The determination of blood-pressure has become more satisfactory in recent years, thanks to the labors of von Basch, Riva-Rocci, and others. The best instru-

ment is that devised by my assistant, Dr. Stanton, which I shall gladly demonstrate to those who are specially interested. In determining blood-pressure we must remember that there is a maximum and a minimum, which respectively correspond with the height of systole and the time just preceding systole. Between these is a mean pressure. It is doubtful if we can ever determine the mean pressure, but a comparison of the highest and the lowest pressures is obtainable, and their comparison gives a working basis for deductions as to the state of the circulation. We have, then, in this instrument a means of determining approximately the condition of blood-pressure, and these results may be utilized in the diagnosis of arterial disease.

If the 4 symptoms I have named were found in arteriosclerosis alone the problem of diagnosis would be greatly simplified, but this is not the case. An eminent authority (v. Basch) does indeed lay great stress on persistent increase of pressure as a symptom of arteriosclerosis, and admits other causes as operative only for short intervals of time. I cannot accept this view as accurate. There are, I believe, numerous and varied conditions of the system, organic and nervous in origin, that elevate pressure nearly constantly, and in which arteriosclerosis has no part except, perhaps, as a consequence. Any one of these conditions may occasion the 4 signs I have discussed.

Aside from this, however, we must further recognize that there is no fixed standard of pressure, and that an arbitrary figure such as 150 mm. of mercury is nothing more than an approximation.

Let me next turn to an aspect of the question that will interest us more directly as physicians. What are the early clinical symptoms that bring the arteriosclerotic patient to his physician? Very often, unfortunately, the beginnings of the disease are so insidious that the patient himself does not realize its presence, any more than the development of advancing age. In other cases the occurrence of arteriosclerosis proclaims itself as a pathologic condition, and differs enough from the gradual physiologic senile arterial hardening to be recognized as a rapidly developing, if not acute, alteration of previous health. Such cases would present themselves to the physician; the other and perhaps larger number would be discovered more or less accidentally.

Among the early symptoms are a change of vigor and of color, and various trivial evidences of reduced vitality. These are especially marked when the myocardium is the first of the organs to suffer. When the patient has been an active man of marked energy and vitality, the change may be pronounced and not rarely it is first noted after some special strain or shock. I cannot forbear recurring again to the importance of the nervous system in the development of the disease. A sudden shock does not, indeed, initiate the malady, but rather renders its effects more pronounced and perhaps hastens its progress, but continued nervous strain, especially when combined with anxiety and irregularities of life, undoubtedly is a contributing cause of arterial disease of greater significance than we usually believe. It is active men of the better class, men who have achieved much and suffered much, though outwardly most successful, that fall early victims to this disease. The easy going, luxurious, and indolent may develop the disease, but not often prematurely and pathologically except as a result of especial excesses.

It would be useless to attempt to detail the many ways in which reduced vigor and lowered vitality may manifest themselves. The friends of the patient or the family may observe the development of these, long before the patient is aware of their existence. Sometimes a supposed nervous breakdown is the form it takes (and I am convinced that neurasthenia is cardiovascular in origin much oftener than is believed); more frequently the symptoms are less pronounced.

With this loss of vigor comes a change of color, a pal-

lor, trifling perhaps at first, but later more and more pronounced. This is most conspicuous about the face, and especially around the mouth, temples, and eyes. In the later stages there is a false appearance of anemia that the experienced readily recognize as the arteriosclerotic facies. Frequently I have examined the blood of such patients and have found no evidence of anemia. The pallor is due to the narrowed arterioles and capillaries, not to impoverished blood.

At this stage, too, the skin is frequently altered in the activity of the sweat glands. While it is as a rule dry, and later becomes persistently so in most cases, in this early stage there may be a marked tendency to occasional sweating, abnormal sweating under exertion, and the like. This may be in part the result of general lowering of vitality. In a measure, however, it is, I believe, a direct vascular and vasomotor phenomenon.

Somewhat of the same sort is the allied renal action seen in many cases of early arteriosclerosis. In the first place, I believe increase in the total amount of urine antedates any actual renal disease, such as we expect, and so frequently find later. This is difficult to prove, but many clinical experiences convince me of its truth. Of greater importance is a disturbance of equilibrium of renal action, a tendency to alterations of polyuria and reduced excretion, and to wide variations in the specific gravity of the urine, with or without marked changes in quantity. The morning urine may show a gravity of 1,025, and the evening urine one of 1,005 to 1,010. I recognize that habits, especially with regard to the drinking of much liquid, play a part in such occurrences, but when arteriosclerosis has begun, it seems to me that the renal permeability is less uniform, and fluctuations are out of proportion to the conditions.

Later, occasional or continuous slight albuminuria makes its appearance and is as a rule significant of quite advanced arterial disease. There are, however, instances in which it occurs before renal changes are marked and in the majority of cases repeated examinations may disclose the occasional appearance of albumin in the urine. Casts are not often found till the kidney has become considerably affected but cylindroids may be discovered much earlier.

When the heart is especially affected symptoms may be in evidence early. I have spoken of the auscultatory phenomena that are found in cases of all sorts and not those alone in which myocardial degeneration is an especial feature. When the heart muscle is affected there may be slight symptoms long before the myocardial disease has become pronounced. Arrhythmia, increased force of the apex impulse and suggestions of dyspnea, are the most important of these. I have elsewhere made allusion to the too common tendency to regard irregularity of the heart in persons of 40, or more, as the result of gastric disturbances, the over-use of tobacco, alcohol, coffee, or tea and of other such causes.¹ It is true that any of these may be the cause of arrhythmia, but much more frequently these causes begin to affect the patient when his arterial system and heart have become diseased and not before. No case should be hastily ascribed to either kind of cause without consideration of the other.

Finally I wish to call attention to the possibility of an early diagnosis by ophthalmoscopic examination. Thickening of the retinal arteries is evidenced by the high light of the arterial image and the compression of the veins where the arteries cross them. Attention has been called to these conditions by de Schweinitz, and in a number of my cases he has found these ophthalmic peculiarities very early in the course of the disease.

It is unnecessary to enter upon any discussion of the late symptoms of arteriosclerosis for the reasons I have given. It is the early stages that need investigation and toward these our thoughts should be directed.

A BACTERIOLOGIC INVESTIGATION OF COMMERCIAL VACCINE VIRUS.*

BY

WILLIAM TRAVIS HOWARD, JR., M.D.,
of Cleveland, O.Professor of Pathology, Western Reserve University; City
Bacteriologist;

AND

WILLIAM H. WEIR, M.D.,

Research Assistant, City Bacteriologic Laboratory, Cleveland, O.

(FROM THE SMALLPOX RESEARCH LABORATORY OF THE CITY
OF CLEVELAND AND THE PATHOLOGIC LABORATORY
OF WESTERN RESERVE UNIVERSITY.)

During the year 1902, samples of vaccine virus, offered for purchase by various manufacturers to the Health Department of Cleveland, were submitted to one of us (Dr. Howard) for bacteriologic examination. On account of the occurrence of several cases of tetanus and a number of cases of badly infected arms, ending, in some cases, in gangrene, following the use of certain viruses used by the city vaccinators in the summer and fall of 1901, this step was deemed necessary for the protection of both the public and the Health Department.

The routine method employed was as follows:

Agar petri plate cultures were made from the contents of single tubes or capsules of glycerinated virus. Ivory points grasped in a sterile forceps were rubbed carefully in melted agar, and then dipped into the media, and the whole poured into petri plates. Both aerobic and anaerobic cultures were made. All the cultures were kept several days in body temperature before counting the colonies. Separate colonies of the various organisms were studied for identification. As a further precaution, mice were inoculated with bouillon containing the virus of at least 3 tubes or points.

The purchase of the virus used by the city vaccine physicians was made from the samples approved by the laboratory. After this action there was a noteworthy decrease in badly contaminated vaccinations, and no further cases of tetanus occurred among persons vaccinated by the vaccine physicians. Samples were submitted by 5 manufacturers, as indicated by numbers. Table I, shows the results of these examinations. Most of the samples were remarkably free from microorganisms. Only three showed staphylococci, and one streptococci. These organisms were not pathogenic for laboratory animals. It will be observed that Virus I always contained actinomyces. *B. tetani* was never cultivated from these samples, and no animals died or appeared ill after inoculation with bouillon containing virus.

Table I gives the results of these examinations.

In December, 1902, it was determined to examine routinely, samples of vaccine virus of these 5 producers, purchased in the open market, through a reliable pharmacist. This work was done by Dr. Wm. H. Weir, under the direction of Dr. Howard. The same methods used in the first series were adopted for the second. The samples of virus were received in unbroken and sealed packages, and kept on ice until cultures were made. It will be observed that the number of colonies is uniformly larger in the second series. Staphylococci and streptococci were often present. The virus from each producer contained actinomyces at one time or another. There was, however, a marked variation in the constancy and numbers of their presence in the different viruses. They were found in every sample, though not in every point or tube, of Virus I. They were present 6 times in Virus II; once (19 colonies) in a single sample of Virus III; 5 times in Virus IV, and once in Virus V. Several varieties of actinomyces were found. A detailed description of these organisms will be given in a separate paper.

Beside the organisms mentioned, various saprophytic bacilli and cocci, and often diphtheria-like bacilli (pathogenic for guineapigs and previously described by other observers) were isolated, *B. tetani* was not found.

The examination of vaccine virus for bacterial impurity has centered chiefly upon the isolation staphylococci, streptococci, and *B. tetani*. The recognition that vaccinia is often complicated with suppuration due to inoculation with pyogenic organisms, at the time of vaccination, incited the various steps which have been taken to lessen the number of organisms present in such virus. Copeman¹ stated in 1895 that 1 or more of 3 species of microorganisms, namely, *Staphylococcus albus epidermidis*, *Staphylococcus pyogenes aureus*, and *Staphylococcus*

* Read at the meeting of the American Association of Pathologists and Bacteriologists, Washington, D. C., May 13, 1903.

cus cereus flavus, were almost universally present in human and calf vaccine lymph, and that *Streptococcus pyogenes* was occasionally present.

It was the paper of Landmann² in 1896, perhaps, which has stirred up most discussion, and stimulated more careful work in this direction. Landmann pointed out that vaccine lymph from 13 German vaccine establishments contained from 50 to 2,500,000 bacteria per

cubic centimeter, and in some samples many of these (in one instance all) were pathogenic cocci. Of 16 samples of virus examined, 3 contained streptococci and 8 staphylococci, all of which were pathogenic for laboratory animals. Kirchner,³ in 1897, studied the bacterial content of the glycerinated lymph of the Hanover vaccine station and failed to find streptococci, but did find once a staphylococcus which was not, however, pathogenic for white mice. In 1898, Migula⁴ found *Staphylococcus aureus* and *Staphylococcus albus* and streptococci (nonpathogenic for laboratory animals), in fresh vaccine lymph from calves. He further found that *Staphylococcus aureus* and *Streptococcus pyogenes* were killed in 3 weeks in 50% glycerin, while 75% glycerin killed *Staphylococcus aureus* in 1 week and *Streptococcus pyogenes* in 2 weeks.

In the same year Dreyer⁵ studied 12 samples of vaccine virus of German production. Direct inoculation of these vaccines into animals resulted in the death of 1 mouse with streptococcus peritonitis, and 1 guineapig after subcutaneous inoculation with streptococci. Five viruses caused in mice, subcutaneous abscesses containing streptococci, and in a sixth mouse there was a small abscess containing a white staphylococcus. He further

inoculated mice and human arms with pure cultures of cocci obtained from these viruses with the following results. There were 27 cultures of staphylococci, 22 of which caused abscesses in mice, and 18 more or less severe inflammation of the human arm. Of 7 cultures of streptococci 3 caused abscesses and death in mice, and all caused more or less severe inflammation of the human arm. Copeman quotes the German Government Board, consisting, among others, of Koch, Pfeiffer and Frosch, as finding in 5 out of 18 samples of vaccine virus, staphylococci, pathogenic for rodents.

The most exhaustive and careful study of the bacterial content of vaccine virus offered for sale in the United States, is that of Rosenau⁶, lately published, and of which he was kind enough to send us proof sheets.

He counted the colonies growing upon agar plates inoculated with the virus on ivory points and in glycerinated tubes of 10 manufacturers in 3 series. In Series I (winter, 1901-2) counts from a large number of ivory points averaged 4,809, and from glycerinated tubes 4,698 colonies. In Series II (spring, 1902) dry points averaged 3,458, and glycerinated tubes 1,058 colonies. In Series III (winter, 1902-3) ivory points averaged 4,895, and glycerinated tubes 29 colonies. Some points contained as many as 44,000 organisms, the highest number from a glycerinated tube was 30,080; a very few points and tubes were sterile. Various staphylococci, some of which are classified as "pyogenic cocci," but none of which apparently was proved to be pathogenic for animals, were commonly found. Streptococci were not found. He did not find *B. tetani* in any virus. The 190 dry points examined averaged 4,354 bacteria per point, and the 244 glycerinated tubes examined averaged 1,742 bacteria per tube, showing a very high bacterial impurity. His work demonstrates conclusively the superiority of glycerinated tubes or points, to ivory points made with fresh "lymph." He justly, we think, attributes the large bacterial contamination of American commercial vaccine virus to carelessness, overconfidence in the germicidal action of glycerin and the sale of unripe or green virus, under the pressure of temporary increased demand. A comparison of our results with those of Rosenau is of interest, as they are to a certain degree mutually supplementary. There is a striking difference in the bacterial content of the virus submitted to the city of Cleveland as samples, which, it was known to the manufacturer, were to be tested bacteriologically (see Table I), and the bacterial content of virus bought by Rosenau and ourselves in the open market unknown to the manufacturers (see our Table II and Rosenau's figures given above). It is fair, however, to state that the small bacterial content of the virus of Table I, in part, may be due to the fact that it was obtained mostly in the summer and early fall months, when the demand is generally at its lowest. On the other hand, there was an extensive epidemic of variola at this time in northern Ohio. The work embodied in our Table II, begins where Rosenau left off—the last of December—and brings the knowledge of the bacterial content of some, at least, of the viruses studied by him down to the end of April, 1903. Most of the virus examined by us in December, January, and February, was badly contaminated. Viruses IV and V never showed a large number of colonies, though staphylococci, streptococci, and actinomycetes were isolated from both. Analysis of Table II shows that of 14 examinations of tubes and points of Virus I, 12 showed staphylococci, 2 streptococci, and 7 actinomycetes; of 18 examinations of Virus II, staphylococci were found in 9, streptococci were found in 10, and actinomycetes in 5; in Virus III, of 3 cultures, all showed staphylococci, and 1 each streptococci and actinomycetes; of 16 cultures of Virus IV, 7 showed staphylococci, 1 streptococci, and 5 actinomycetes; while of 12 cultures from Virus V, 7 showed staphylococci, 4 streptococci, and 1 actinomycetes. Out of a total of 63 cultures from separate tubes or points, staphylococci

were isolated in 38, streptococci in 18, and actinomycetes in 20. In a number of cultures streptococci were the most numerous organisms present, and in some all or nearly all the colonies were streptococci. In 1 plate in which the colonies were too numerous to count, there was a pure culture of streptococci. Tubes or points with very low counts (2, 8, 10, 1, 3, 9, etc.) may contain staphylococci, streptococci, or actinomycetes. Actinomycetes may be found in plates with either high or low counts. The percentage of glycerin used is evidently not strong enough to kill the spores. Experiments are now being carried out to determine the strength of glycerin, and the time needed for this.

The 9 varieties of actinomycetes isolated, form the subject of a second paper. Sufficient to say here that few of them conform to the descriptions of previously recognized forms and that none of them causes suppuration or actinomycotic nodules in laboratory animals. The latter point is, however, of little value, for it is well known it is the exception, rather than the rule, for actinomycetes isolated from lesions in man and cattle, to cause lesions in laboratory animals.

On account of the difficulty in obtaining mice, it was not possible to test the pathogenicity of all the strains of streptococci. The few which were tested proved to be pathogenic.

THE METHYLENE-BLUE EOSIN STAINS.

BY

WALTER BAUMGARTEN, M.D.,

Assistant in Medicine, Johns Hopkins University.

[From the Clinical Laboratory of the Johns Hopkins University. Service of Professor Osler.]

Considering the increasing use of blood stains consisting of methylene-blue and eosin, and the confusing multiplicity of names applied to modifications of what is essentially one method, it has seemed well to describe briefly the development of mixtures of methylene-blue and eosin as stains for blood, and to gather together the various modifications of the combination of these two stains.

As Ehrlich¹ originally demonstrated, mixtures of aqueous solutions of basic and acid staining components of the anilin stains result in the formation of a neutral stain in which the basic stain forms the base, the acid stain the acid portion, these having previously existed respectively as a base combined with an inorganic acid, and as an acid combined with an inorganic base. In staining a cell, such a neutral stain combines with the neutral substances of the cell—substances which are not stained by either component of the neutral stain. The alkaline substances of the cell, however, split up the neutral stain, and combine with its acid component, while the acid substances combine with the basic component. Neutral stains, however, are practically insoluble in water, but soluble in an excess of the acid component, and in at least one instance—methylene-blue²—in an excess of the base. Mixtures, therefore, of methylene-blue and eosin form a neutral stain, which, being insoluble in water must be redissolved in an excess of one or the other. In blood-films stained in such a stain, the red blood-corpuscles and the granules of the eosinophiles take the eosin, the nuclei of the leukocytes and

the basophile granules, the methylene-blue, and the neutrophile granules the neutral stain (methylene-blue-eosin).

Methylene-blue is a basic stain, which, in its ordinary commercial form, is combined with hydrochloric acid, forming a neutral salt, the tetra methylthionin hydrochlorate. This has the following formula:

This salt, even in its purer forms, contains traces of its own decomposition products—some sorts containing more than others. These decomposition products were isolated in 1885 by Bernthsen.³ He showed that the stain (the base) itself, and its oxide, were quite unstable, and easily underwent either oxidation, reduction, or hydrolytic splitting, and that in alkaline solution all these processes occurred together. The products of these processes are 3 bases, all of which possess staining properties; they are respectively:

methylene-azure, $(\text{CH}_3)_2 \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} (\text{CH}_3)_2 \text{---}$,

leuko-methylene-blue, $(\text{CH}_3)_2 \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} (\text{CH}_3)_2 \text{---}$,

and methylene-violet, $(\text{CH}_3)_2 \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} \text{C}_6\text{H}_4 \text{---} \text{N} \text{---} (\text{CH}_3)_2 \text{---}$

Of these, methylene-violet plays no part in aqueous solutions on account of its insolubility in water. On the first, methylene-azure, depends the staining picture which is given by most of the recently proposed stains, consisting of methylene-blue and eosin.

The object in view in the older mixtures of methylene-blue and eosin intended for blood-staining, of which the stains of Chenzinky⁴ and of Plehn⁵ are best known, was to obtain a permanent mixture which would not throw down a precipitate. In order to prevent the precipitation of neutral stain which is formed, a sufficient excess of methylene-blue was added to secure its solution. This excess, however, was enough to prevent the staining by the neutral stain. These mixtures stain the red blood-corpuscles, the nuclei of leukocytes, the eosinophile and basophile granules, and malarial parasites, but fail to stain the neutrophile granules.

In 1891 Romanowsky⁶ described, in blood-films of cases of tertian malaria, a distinctive violet stain for chromatin, obtained with a mixture of concentrated aqueous solutions of methylene-blue and eosin. His stain appears to have been devised primarily for the purposes of a general blood stain, in which were followed the principles laid down by Ehrlich in regard to neutral stains. Having, apparently accidentally, used an aqueous solution of methylene-blue old enough to have a mold form upon its surface, he observed that in these films the chromatin material of the leukocytes stained from a dark to a reddish violet, and that similarly (carmin-violet) stained areas appeared in the heretofore non-staining portion of the malarial parasites. Because these areas took up the same stain as the chromatin of the nuclei of leukocytes, and as he frequently observed them (the areas in the nonstaining portions of the parasites) to assume karyokinetic figures, Romanowsky concluded that they represented the chromatin material of the nucleus of the malarial parasite, and that the remainder of the nonstaining portion was the achromatic zone of the nucleus. In addition to this peculiar chromatin staining, a differential staining of the leukocytes took place; the eosinophile granules stained an intense rose-red, the neutrophile granules a dark violet, the protoplasm of mastzellen dark blue, and of lymphocytes a lilac

blue; the blood-platelets stained a dark reddish-violet, and the bodies of the malarial parasite a blue.

The most intense violet stain of chromatin material Romanowsky obtained just at the moment that the precipitate began to appear in the mixture of methylene-blue and eosin. In its original form the mixture consisted of 1 cc. of a concentrated (saturated?) aqueous solution of methylene-blue and 2 cc. of a 1% aqueous solution of eosin. With this he obtained fairly well-stained specimens in from $\frac{1}{2}$ to 1 hour, but much more intense staining in 2 or 3 hours. Later, however, he used a more dilute mixture in which it was necessary to stain for 24 hours; this mixture was made up of equal parts of a half saturated solution of methylene-blue and a 0.5% solution of eosin.

This marked a definite advance in the means of study of the structure of the malarial parasite. Great difficulty was, however, experienced by others in obtaining Romanowsky's results, and his method was subjected to a long series of modifications which were intended to give more certain and more rapid stains, and many of which bear independent names.

Very few (Korolko,⁷ Sacharoff⁸) succeeded in obtaining the violet stain in chromatin by following Romanowsky's technique, and several years elapsed before it was discovered that certain makes of methylene-blue and of eosin give much more uniformly reliable results than others, and that the usual negative results were due to differences in the methylene-blue rather than in the eosin. Gautier,⁹ in 1896, found that with methylene-blue made by the Bädische Soda-Anilinfabrik, marked C or B G N, the staining of the chromatin of both malarial parasites and leukocytes according to Romanowsky could be uniformly obtained. He also specified as necessary an eosin marked A, made by the same firm, but this afterward proved immaterial.

Gautier's observations were originally published in Russian, and remained unrecognized until they were rewritten in French in 1897, and in German in 1898. In the latter year Ziemann¹¹ published the results of an extended examination of various sorts of methylene-blue. He reached the conclusion that none of the methylene-blue, which forms a double salt with zinc chloride, was suitable for Romanowsky's stain, and that methylen-blau med. pur. (Höchst) and methylen-blau rectificat. n. Ehrlich (Grübler), both being simple tetra-methylthionin hydrochlorate, most frequently gave the violet chromatin stain. He further pointed out that, by using dilute solutions, a stain is obtained equally as good as that obtained with Romanowsky's concentrated solutions, but that in using them it was of even greater importance than in using concentrated solutions to adhere to those proportions which were found to give the best stain. He used a 1% aqueous solution of methylene-blue and a 0.1% solution of eosin, and found the best proportion between the two solutions to vary from 1:4 to 1:7.

Little attention has apparently been paid to the fact that soon after Romanowsky's description of his stain, Malachowski¹⁰ (of Breslau) published a method by which, several years previously, he had found in blood-films stained for 24 hours in a preparation of Plehn's stain, the same violet staining of chromatin. He describes a substance in the body of the malarial parasite which takes a reddish-violet stain, and is sharply differentiated from both the red blood-corpuscle and the body of the parasite; he also describes the nuclei of leukocytes as dark violet. As many subsequent workers have done, Malachowski failed to get similar stains when his original preparation had become exhausted. In casting about for suitable methylene-blue he found that it should be employed in dilute alkaline solution. He finally employed a solution made alkaline with borax, and stained first with eosin, then with the alkaline solution of methylene-blue. With this he again obtained the violet chromatin stain.

Ziemann,¹² soon after the original description of his modifications and improvements in Romanowsky's stain, advised the addition of borax to his former solutions of methylene-blue. He was led to make this addition by the fact that Loeffler's alkaline methylene-blue intensifies the methylene-blue stain, and he cites Malachowski's previous use of borax. He supposed the alkali to dissolve the "third stain," and tried, in addition to borax, ammonium carbonate, sodium carbonate, sodium and potassium hydroxide.

Neither Romanowsky, nor the men that followed him, gained any definite knowledge of the substance which gave the violet color to chromatin. The matter remained unsolved until Nocht¹³ suggested that this substance might arise from impurities contained in methylene-blue, as well as from combinations of methylene-blue and eosin, as had hitherto been assumed. Unna's alkaline polychrome methylene-blue was known to contain decomposition products of methylene-blue, usually referred to as methylene-red and methylene-violet. This, after neutralization with acetic acid, Nocht added to a concentrated solution of ordinary methylene-blue in the hope that it would intensify the violet chromatin stain. This conjecture was borne out by subsequent results. He found that with chloroform a substance could be extracted from a solution of polychrome methylene-blue which was dark red in color, was easily soluble in water, becoming reddish-violet in aqueous solution, and decomposed easily in dilute solution and on heating. For want of a more accurate term, he called this "Rot aus methylen-blau." He found that in aqueous solution it stained the chromatin of the younger forms of malarial parasites in the reddish-violet color of Romanowsky's stain, but that it failed to stain the older forms, and the nuclei of the leukocytes. Combined with eosin it stained more actively, and stained best when dissolved in a mixture of methylene-blue and eosin. It stained most intensely, but unevenly, in alkaline solution, though the alkali plays no part in the staining, but is simply a means of increasing the "Rot aus methylen-blau." To Nocht, therefore, belongs the credit of isolating the stain which gives the violet chromatin stain; he described some of its properties and reactions, though he did not determine its chemical structure.

In his original procedure Nocht diluted 3 or 4 drops of a 1% aqueous solution of eosin with 1 cc. or 2 cc. of water (equal to a 0.2% solution), then added neutralized polychrome methylene-blue until the eosin color of the mixture just disappeared. In this mixture staining required several hours, up to 24. Later in the same year he published a method¹⁴ of making polychrome methylene-blue, with which, using the same technique as before, he obtained good stains in 5 to 10 minutes.

The methods of Maurer¹⁵ and Ruge¹⁶ are modifications of Nocht's procedure, which differ from it in the ways of making the polychrome methylene-blue, or in increasing the rapidity or intensity of the stain. Maurer emphasized, and applied to mixtures of alkaline methylene-blue, and eosin, what Ziemann had pointed out for ordinary methylene-blue, that to obtain the most intense violet stain it is most important to adhere accurately to the proper proportions of the two solutions; and also that the more concentrated the original solutions, the more rapidly disappears the power of the mixture to stain intensely. Ruge, starting with the assumption that the appearance of a precipitate in a mixture of alkaline methylene-blue and eosin indicated the point of saturation of the mixture with the "third" or violet chromatin stain, found that the violet stain could be obtained in mixtures to which less than half the eosin had been added which was necessary to produce a precipitate. This gave him a method of avoiding the precipitate. He found that this could be still further improved by using very dilute solutions, in which, however, the eosin had to be added in proportion much nearer the point of

saturation. Ruge obtained the best results with a 0.02% solution of methylene-blue, and by heating the mixture while staining.

Lazear¹⁷ has given directions for carrying out Nocht's method of staining, which, though they contain nothing new, are so precise and clear that they are included in the subsequent outline.

In 1899 Laveran¹⁸ suggested another method of modifying methylene-blue, which, though he does not state it, is apparently designed to increase the decomposition products in an aqueous solution of methylene-blue. He sets free the methylene-blue base by adding to a concentrated solution of methylene-blue (Höchst) a quantity of freshly precipitated silver oxide (Ag_2O). As before stated, commercial methylene-blue is combined with hydrochloric acid; in Laveran's method of preparing the methylene-blue solution a certain proportion of the methylene-blue is decomposed by the silver oxide, so that silver chloride is precipitated and the methylene-blue, which easily breaks down, is left in solution. According to Bernthsen³ the latter decomposes partly into methylene-violet, which is soluble with difficulty in water, and partly into methylene-azure.

In 1901 Michaelis¹⁹ called attention to Bernthsen's³ work on the chemistry of the methylene-blue group, and identified Nocht's "Rot aus methylen-blau," formed in alkaline solutions of methylene-blue, with Bernthsen's methylene-azure. Of the three decomposition products of methylene-blue in alkaline solution—methylene-azure, leukomethylene-blue, and methylene-violet—methylene-violet as a base is insoluble in water and as a salt does not stain, and leukomethylene-blue is further decomposed, so that both these bases may be disregarded as the source of the violet chromatin stain. Furthermore, the red substance extracted with chloroform from alkaline solutions of methylene-blue gives a green color when dissolved in concentrated inorganic acids. This is due to the formation of a triple acid salt of methylene-azure, each nitrogen group, of which there are three in methylene-azure as well as in methylene-blue, combining with an acid group. Derivatives of methylene-blue, on the other hand, which contain only two nitrogen groups, among which are methylene-violet and leukomethylene-blue, give a blue color which dissolves in concentrated inorganic acids. In alkaline aqueous solution methylene-azure is red, in neutral or acid solution blue, just as is "Rot aus methylen-blau."

In describing the staining power of methylene-azure Michaelis confirms Nocht's description of "Rot aus methylen-blau." Methylene-azure alone, in aqueous solution, stains chromatin material only very slowly, and among the malarial parasites only the hyaline forms. With the addition of eosin the power of the stain is greatly increased. Together with Wolff,²⁰ Michaelis showed that methylene-azure combines with eosin to form a neutral stain, just as does methylene-blue; he found this neutral stain sufficiently soluble in hot water to be used as a stain. Michaelis considers it useless to use isolated methylene-azure for staining purposes, as it can be easily prepared in alkaline solutions of methylene-blue. He suggests a modification of Nocht's method of preparation which greatly simplifies the neutralization, and shortens the usually tedious process. He adds a definite quantity of decinormal NaOH to a 1% aqueous solution of methylene-blue; after heating this alkaline solution in order to hasten the formation of methylene-azure, he exactly neutralizes it with a quantity of decinormal H_2SO_4 equal to the NaOH previously added.

Goldhorn²¹ has suggested a modification in which the eosin and polychrome methylene-blue are used one after the other in staining the blood-film. In addition to the separate use of the two stains, the procedure differs from others in the mode of preparation of the polychrome methylene-blue. This is made by heating a dilute aqueous solution of methylene-blue with lithium carbonate, which, according to Goldhorn, gives more sat-

isfactory results than sodium or potassium hydrate, or potassium carbonate. This method gives the results perhaps, more rapidly than any of the other methylene-blue-eosin stains, as the staining with each solution is a matter of seconds, at most of 2 minutes. The polychrome methylene-blue easily decolorizes the eosin.

It appears, therefore, that the substance in mixtures of methylene-blue and eosin which gives to chromatin material the reddish-violet color first described by Romanowsky is methylene-azure, an oxidation product of methylene-blue. It is present as an impurity in most sorts of methylene-blue, in some in greater quantity than in others, but particularly in alkaline solutions in which all the methylene-blue may in time be decomposed. This was discovered empirically before the stain was identified with the substance isolated by Bernthsen. Methylene-azure is a base, as is methylene-blue, and as such forms with eosin a neutral stain (methylene-azure-eosinate?) which is not easily soluble in water, more so, however, than the neutral stain of methylene-blue and eosin. This is split up by acidophile and basophile substances, the basic methylene-azure staining basophile substances a reddish-violet. The ease with which the violet stain is masked depends on the proportion between the methylene-blue and the methylene-azure contained in a mixture with a given amount of eosin. Ziemann demonstrated this very clearly, and on this fact rest the failures in former years.

The modifications of Romanowsky's stain, so far presented, are mixtures of aqueous solutions of methylene-blue and eosin. A second series of stains has arisen out of the solubility of neutral stains in pure alcohols. The solubility of neutral stains in the alcohols was, however, not made use of until 1899. In that year two men, Jenner²² and Rosin,²³ published methods of staining with neutral stains in alcoholic solution, the former describing a method for staining blood, parasites, and bacteria, with the neutral stain formed by ordinary methylene-blue and eosin, the latter suggesting the utility of the method for general histologic purposes, and employing neutral stains formed by methyl green and methyl orange, malachite green and rubin, methylene-blue and picric acid, magenta red and picric acid. Both described the properties of the stains with which they worked. The stain is precipitated out of dilute alcoholic solution as grass green metallic crystals, and out of aqueous solutions as a dark green amorphous powder. It is insoluble in hot or cold water, soluble with a green fluorescence in pure ethyl and methyl alcohol. Jenner adds that it is soluble in chloroform and in anilin oil, and melts at 227°C.; Rosin that its solutions have a neutral reaction, and a characteristic spectrum. Jenner used methyl alcohol as solvent, Rosin ethyl alcohol.

Jenner was the first to employ the solvent of his stain, methyl alcohol, as the fixing agent for blood-films, so that fixing and staining went on at the same time. His whole fixing and staining procedure consumes less than 5 minutes, which is a great saving of time in comparison with the mixtures of aqueous solutions (with the exception of Goldhorn's procedure). In Jenner's stain the red blood-corpuscles stain a rose red, nuclei of leukocytes blue, neutrophile granules pale red, basophile granules dark violet, eosinophile granules an intense red, malarial parasites and bacteria blue. As a differential stain for leukocytes it has proved uncertain in staining neutrophile granules. The staining of the chromatin in the nuclei of malarial parasites is seldom accomplished, rarely satisfactory, and was not among the original purposes of the stain.

Neither Jenner nor Rosin refer to the production of the violet chromatin stain with alcoholic solutions of neutral stains. This application was made almost simultaneously, in 1901, by Reuter²⁴ and Leishman,²⁵ the former following Rosin, the latter Jenner. Both used an alkaline solution of methylene-blue, one, therefore,

which contained much methylene-azure. The precipitate (neutral stain) obtained by mixing this with eosin, was dissolved by Reuter in pure ethyl alcohol, by Leishman in pure methyl alcohol. Reuter prepared the blood-films by previous fixation in absolute alcohol and ether. He then stained for from one-half to three hours in a mixture of 1 or 2 drops of the full strength stain diluted with 1 cc. to 2 cc. of water. In such a mixture a precipitate forms only very slowly, and Reuter found that clearer and more brilliant pictures were obtained in this way than by using the full strength stain. So stained, the red blood-corpuscles assume a pale orange color, the cytoplasm of malarial parasites a blue, and the chromatin of their nuclei a reddish-violet.

Leishman, following Jenner, fixed his blood-films at the same time that he stained. He found, however, that a half a minute was sufficient for fixing, and hit upon the same device as did Reuter. After allowing a half minute for fixation in the full strength stain, he adds water drop by drop until the stain becomes semitranslucent, and its surface becomes covered with a metallic scum. So diluted, he allows the stain to act for about 5 minutes. In this stain the nuclei of leukocytes take a violet color, the neutrophile granules a red, the eosinophiles a dark pink, and the basophile granules a purplish-black, malarial parasites a pale blue, the chromatin in their nuclei a carmin red; the red blood-corpuscles may stain either a pale red, or a greenish color. Leishman has also used his stain for staining bone marrow, spleen pulp and bacteria.

Wright²⁶ modified Leishman's stain in that he simplified the process of making the alkaline methylene-blue, and made changes in the relative amount of time devoted to fixing and staining. With the undiluted stain he fixes for 1 minute, then dilutes with water, and continues the staining for 2 or 3 minutes. The nuclei of lymphocytes stain dark purplish in this stain, the nuclei of the large mononuclears blue, of the polymorphonuclear leukocytes a blue or dark lilac, of myelocytes a blue or purplish. The cytoplasm of malarial parasites stains blue, the chromatin of their nuclei forms a lilac, through a red, to a black, according to the duration of the staining.

The methods of making the alkaline methylene-blue used by Reuter and by Leishman are almost identical. Both add 0.5% Na_2CO_3 to a 1% methylene-blue solution. Reuter then "ripens" his solution by keeping it in a thermostat for 3 days at a temperature of 50° to 60° C.; Leishman, instead, heats for 12 hours at 65° C, and then allows his solution to stand at room temperature for 10 days. Wright uses 0.5% NaHCO_3 in a 1% methylene-blue solution, and shortens Leishman's procedure in that he heats this solution for 1 hour in a sterilizer at 100° C.

Reuter in diluting his alcoholic solution of the stain with water causes a fine precipitate, which sometimes settles on the blood-film. Leishman uses a saturated solution for the fixing of the blood-film, which easily precipitates particles of the stain before it is diluted with water. Wright has avoided this precipitation by making only an 80% solution of his stain. Both Leishman and Wright stain for so short a time that the precipitate formed after dilution with water does not often settle on the blood-film.

It may again be pointed out that those mixtures of methylene-blue and eosin which stain the chromatin material of the cell in varying shades of violet depend for this characteristic not upon methylene-blue, but upon its oxidation product, the methylene-azure of Bernthsen; and that the solutions in alcohol (ethyl or methyl) of neutral stain—Reuter, Leishman, Wright—which has been prepared from polychrome (alkaline) methylene-blue probably contain a large amount of methylene-azure eosin in proportion to the methylene-blue eosin.

In conclusion, I wish to acknowledge my indebtedness to Dr. C. P. Emerson, at whose suggestion this review was made.

Chenzinsky's⁴ stain:

Concentrated aqueous solution of methylene-blue
Distilled water equal parts.
To this is added an equal quantity of 0.5% solution of eosin in 60% alcohol. Stain blood-films 4 to 5 minutes. Red blood-corpuscles stain a rose-red, nuclei of leukocytes, blue, and malarial parasites blue.

Plehn's⁵ stain: (This is a modification of Chenzinsky's stain.)

Concentrated aqueous solution of methylene-blue
Distilled water equal parts.
To this add one-half the equal volume of a 0.5% solution of eosin in 60% alcohol. Filter before use. Fix blood-films in absolute alcohol for 7 to 10 minutes. Stain from a few minutes to 24 hours. Red blood-corpuscles and eosinophile granules stain a rose-red. The nuclei of leukocytes stain a dark-blue, and malarial parasites a light-blue.

Romanowsky's⁶

1. The concentrated stain.
To a saturated aqueous solution of methylene-blue 1 part
Add a 1% aqueous solution of eosin 2 parts
Mix these in a watch crystal, stirring with a glass rod. Prepare the stain only 1 to 2 minutes before use. Float blood-films on the surface of the stain. One-half to one hour is sufficient to give the violet chromatin stain. Two to three hours are necessary to give the most intense stain.

2. A more dilute form of the stain.
A saturated aqueous solution of methylene-blue
Distilled water equal parts.
To this add an equal volume of 0.5% aqueous solution of eosin. Mix in watch crystal as in 1. Stain for 24 hours. Wash in distilled water. Dry.
Romanowsky used a solution of methylene-blue over the surface of which mold had formed.

Fixing of blood-films: Heat for 30 minutes at 105° to 110° C.

Staining reactions:
Red blood-corpuscles stain rose-red.
Leukocytes—nuclei, stain dark violet; those of eosinophiles a reddish-violet; eosinophile granules stain intense red; neutrophile granules stain dark violet; protoplasm lymphocytes stain dark blue; mastzellen stain dark blue.
Blood-platelets stain dark, reddish-violet.
Malarial parasites—body, stains blue; center of achromatic area stains carmin violet.

Korolko's⁷

Solution A.—A saturated aqueous solution of methylene-blue, 3 months old and filtered before use.

Solution B.—A 1% aqueous solution of eosin.
To make up the stain add to 2 cc. or 3 cc. of solution A, from 3 cc. to 5 cc. of solution B until a violet color is obtained, and a fine granular precipitate is formed. Mix the solutions in a narrow cylinder, and stir with a glass rod.

Stain in this mixture 15 to 24 hours, if possible, at a temperature of 30° C.

Fix blood-films by heating for 1 hour at 105° to 110° C.

Staining reactions:
Red blood-corpuscles stain blue.
Leukocytes—nuclei stain dark violet; cytoplasm stains blue.
Blood-platelets stain light violet.
Malarial parasites—nuclei, chromatin portion stains deep violet; cytoplasm stains light blue.

Sacharoff's⁸

Solution A.—Saturated aqueous solution of methylene-blue diluted one-half with water.

Solution B.—A 1% aqueous solution of eosin (Grübler, w. g.)
To Solution A, Sacharoff adds Solution B, constantly stirring the mixture, until a granular precipitate begins to form. (Sacharoff's only reference to the sort of methylene-blue used is, that if no precipitate forms the methylene-blue employed is not suitable for this stain.)

After the precipitate begins to form Solution B is added drop by drop. After each drop a blood-film is covered with a portion of the mixture, and the series of films so obtained is placed in a moist chamber and allowed to stain for 24 hours. Of these usually one or two will be found to be good.

The films are fixed "according to Ehrlich" by heat.

Gautier's⁹

Followed Romanowsky's technic.
Employed for the methylene-blue solution:
Methylen-blau (Badische Soda-anilin fabrik), Marke C or BGN;
For the eosin solution: eosin (Badische Soda-anilin fabrik), Marke A.

Ziemann's¹¹ Original modification:

Solution A.—1% aqueous solution of methylene-blue med. puriss. (Höchst), at least 24 hours old, and containing no undissolved particles.

Solution B.—0.1% aqueous solution of eosin—freshly prepared from an aqueous 1% stock solution of eosin.

To determine the proportion of the two solutions, and the length of time which gives the best results, make mixtures of solutions A and B in proportions ranging from 1:4 to 1:7. For each such mixture prepare three watch crystals each containing a blood-film placed face down. Pour a portion of the mixture into each of the 3 watch crystals, and remove 1 film every 10 minutes. Ziemann obtained the best results from mixtures having the proportion of 1:5 or 1:6 in which he stained for 20 to 40 minutes. It is important to measure out the solutions with the greatest possible accuracy. According to Ziemann, the finding of the correct proportion between the two solutions and the proper staining period requires about 1 hour.
Wash the films in distilled water. They may be decolorized in a 1% or 1% solution of acetic acid or HCl; or in a 1% aqueous solution of methylene-blue.

Subsequent modification:¹²

Solution A.—
Methylene-blue med. puriss. (Höchst) 1 g.
Borax 2 g. to 4 g.
Usually 2.5 g.
Distilled water 100 cc.

Solution B.—
0.1% aqueous solution of eosin ("A. G." Höchst).

To make up the stain, mix: { Solution A . . . 1 part
Solution B . . . 4 parts
Stain blood-films for 5 minutes; 8 to 10 minutes stains the chromatin almost black. Fix films either by passing through the flame, or in absolute alcohol for 20 minutes to 30 minutes.

Malachowski's¹⁰

Stain in an aqueous solution of eosin (percent not stated, time not stated). Then stain in "a very dilute aqueous solution of borax—methylene-blue" (percent not stated, no time stated). Staining is performed rapidly by applying heat; this, however, gives very uneven results. When carried on in the cold, the stain is uniform, but may require 24 hours. Blood-films are fixed in absolute alcohol (time not stated).

Nocht's¹³ Original method:

Unna's polychrome methylene-blue is neutralized with dilute acetic acid.

Solution A.—1 cc. of this neutralized polychrome methylene-blue is mixed in a watch crystal with a saturated aqueous solution of ordinary methylene-blue until its red color disappears, and the solution becomes blue.

Solution B.—Dilute 3 drops to 4 drops of 1% aqueous solution of eosin with 1 cc. or 2 cc. water.

Add solution A drop by drop to solution B until B is dark blue; a precipitate has then formed. In this mixture blood-films are to be stained for several hours up to 24 hours. Fix films in alcohol or by heat.

Subsequent modification:¹⁴

Solution A.—The polychrome methylene-blue solution. To a 1% aqueous solution of methylene-blue add 1.0% or 0.5% Na₂CO₃. Heat at 50° C. to 60° C. for several days.

Solution B.—Dilute 2 or 3 drops of 1% aqueous solution of eosin with 1 cc. or 2 cc. water.

To solution B add solution A drop by drop until the mixture is dark blue and has lost its eosin tint. To stain, float blood-films, face down on this mixture for 5 to 10 minutes.

Lazear's¹⁷ execution of Nocht's modification:

Solution A.—The polychrome methylene-blue solution. To a 1% aqueous solution of methylene-blue add 1% of NaOH. Heat in a water-bath for several hours. Cool, then filter.

To neutralize this solution, add dilute acetic acid until blue litmus paper is turned red above the line which the methylene-blue stains. Then add more alkaline polychrome methylene-blue until the solution just fails to turn blue litmus red. To this neutralized solution add an equal volume of distilled water; then a saturated solution of ordinary methylene-blue until the polychrome methylene-blue has lost its red color—about 1 part of the former to 10 parts of the latter.

Solution B.—A 0.2% aqueous solution of eosin.

With burets determine the proportions of the 2 solutions, on mixing which, a fine slack precipitate is obtained, and a scum forms on the surface of the mixture. This may require 1 part of Solution A to 3 parts of Solution B, or the reverse. Once determined, the proportion remains constant.

Blood-films are fixed for 1 to 2 minutes in a 1% solution of formalin in 95% alcohol.

To stain: Remove scum from the surface of the stain with filter paper. Place the films face down in the stain. Stain for 3 to 24 hours.

Maurer's¹⁵

Solution A.—To a 1% aqueous solution of methylene-blue (med. puriss., Höchst, or Anilin-blau, Merck) add 0.5% Na₂CO₃. Expose to the sun for 2 or 3 days, or keep at room temperature for 8 days. Add 1% formalin to prevent formation of mold.

Solution B.—A 0.1% aqueous solution of eosin (Grübler, w. g.). Maurer gives 2 methods of procedure: (1) With rapid; (2) with slow staining. He also indicates grades of intensity of staining.

I.—Rapid staining. The blood-film is placed at an angle face down on a glass slide, one edge being elevated. Solutions A and B are used in their full strength.

1. Grade of intensity of staining is obtained by mixing 2 parts of Solution A with 20-12 parts Solution B.
2. Grade of intensity of staining is obtained by mixing 2 parts of Solution A with 10-4 parts Solution B.
3. Grade of intensity of staining is obtained by mixing 2 parts of Solution A with 3-2 parts Solution B.
4. Grade of intensity of staining is obtained by mixing 2 parts of Solution A with 2-1 parts Solution B.

As the period of most intense staining lasts only a few seconds after the mixture is made up, it is necessary to stain *immediately*, and the staining need not be carried on for more than a few minutes.

II.—Slow staining. 1 cc. Solution A is mixed with 25 cc. water. 1 cc. Solution B is mixed with 25 cc. water.

These solutions are then mixed in a beaker. Films to be stained are immersed in the stain *immediately*.

1. Grade of intensity of staining is obtained in 10 minutes.
2. Grade of intensity of staining is obtained in 20 minutes.
- 3 and 4. Grades of intensity of staining are obtained in $\frac{1}{2}$ hour to 1 hour at the longest.

In Grade 1 the nuclei of leukocytes stain blue or bluish violet.

Blood-platelets stain pale blue.

Malarial parasites—cytoplasm stains pale blue; chromatin stains ruby red.

In Grade 2 nuclei of leukocytes stain violet red.

Chromatin of malarial parasite stains brilliant red.

In Grade 3, Grade 2, with Schüffner's mottling of infected red blood-corpuscles, in addition.

In Grade 4, Grade 3 and in addition in malarial parasites the achromatic area about the chromatin stains faintly red.

Ruge:

Preparation of the solution of polychrome methylene-blue.

To a 1% aqueous solution of methylene-blue add 0.1% NaOH. Heat this solution—short of boiling—3 or 4 times. Add 0.2% NaOH, and repeat the heating.

To make up the stain: Titrate a 1% aqueous solution of eosin against the solution of polychrome methylene-blue until a precipitate just appears; 1 cc. of the polychrome methylene-blue usually requires from 0.3 to 0.6 eosin solution. Then dilute both solutions to make 0.02% solutions. The best violet stain is obtained when a quantity of eosin is added to the methylene-blue equal to one-half that required to produce a precipitate. This, however, must be determined for each individual solution.

Staining: Blood may be stained on either coverslips or slides.

Coverslips: Place blood-films in watch crystal, cover with the stain. Heat until the fluid steams, and a metallic scum forms on its surface. This requires 1 to $\frac{1}{2}$ minutes. Alternately heat and cool for 6 minutes. Wash in water. Dry.

Slides: Cover the blood-film with the stain. Heat for 2 minutes until this steams, and a scum forms on its surface. Let cool for 2 minutes. Heat again for 2 minutes. Wash in water. Dry.

Laveran:¹¹

In a 150 cc. flask dissolve "some" AgNO_3 in 50 cc. or 60 cc. of water. When dissolved fill the flask with a solution of NaOH (percent not given). Wash the precipitate of AgO with distilled water to remove the excess of NaOH and the NaON s formed. Then add a saturated aqueous solution of methylene-blue medicinale (Höchst) and let the mixture stand for 7 or 8 days, shaking it occasionally. Decant. The product so obtained Laveran terms "bleu Borrel."

To stain Laveran mixes

Methylene-blue (bleu Borrel)	1 cc.
Eosin 0.1% aqueous solution	4 cc.
Distilled water	6 cc.

Stain 12 to 24 hours. Rinse in water. Wash in 5% aqueous solution of tannin for 1 to 2 minutes. Wash in water. Dry. Films are previously fixed in absolute alcohol for 20 minutes.

Michaelis:¹²

Solution A.—The polychrome methylene-blue solution. To 200 cc. of a 1% aqueous solution of methylene-blue, add 10 cc. $\frac{N}{10}$ NaOH solution. Boil the mixture for 15 minutes.

After cooling neutralize with 10 cc. $\frac{N}{10}$ H_2SO_4 solution.

Solution B.—A 0.1% aqueous solution of eosin. To 2 cc. of Solution A, add 10 cc. of Solution B. Stain blood-films in this mixture for 15 minutes. Wash rapidly in running water.

Blood-films must be thin; those in which the cells remain spherical do not take the violet chromatin stain. Fix blood-films for 1 hour in absolute alcohol.

Goldhorn:¹³

Preparation of the solution of polychrome methylene-blue. **Solution A.**—(Merck's medicinal methylene-blue; Grübler's methylene-blue rectified, and methylene-blue [Koch]). Dissolve 2 gm. methylene-blue in 300 cc. warm water. Add to this 4 gm. lithium carbonate, shaking constantly. Heat in an evaporating dish on a water-bath, the water touching the dish. Stir the solution occasionally. Remove in 15 to 20 minutes. Do not filter. Set aside for several days. Then add dilute acetic acid (5%) until the solution is only faintly alkaline.

Solution B.—A 0.1% aqueous solution of eosin. Fix blood-films in methyl alcohol for 15 seconds. Wash in running water. Stain in Solution B for 7 to 30 seconds. Wash. Stain in Solution A for 30 seconds to 2 minutes. Wash thoroughly in running water. Dry by agitating in air, not between filter paper.

The eosin may be added to the methyl alcohol (enough to make a 0.1% solution); or Solution B may be added to Solution A (1:4), but this easily produces a precipitate (the neutral stain). These give good results. Mixtures of methyl alcohol, eosin, and polychrome methylene-blue give poor results.

The depth of the chromatin stain depends on the length of staining. To stain the chromatin of half-grown malarial parasites, 1 to 2 minutes are necessary, while the chromatin of the hyaline forms stain in 10 seconds.

Repeated staining may improve the chromatin violet. To do this the blood-film may be stained with Solution B five seconds, with Solution A ten seconds.

Jenner:¹⁴

Preparation of the neutral stain.

In an open beaker mix equal parts of 1.2 or 1.25% aqueous solution of eosin (Grübler), 1% aqueous solution of methylene-blue med. (Grübler). Let stand for 24 hours. Filter. Dry the precipitate obtained. Wash the precipitate with distilled water and dry again.

The staining solution:

For use dissolve 0.5 gm. of the precipitate in 100 cc. pure methyl alcohol (Merck "for analysis"). Jenner gives no particular method of fixation.

Staining:

Stain in the solution for 1 to 3 minutes, covering with a watch crystal. Pour off stain quickly and rinse in water till film is pink (5 to 10 seconds).

Staining reaction:

Leukocytes—nuclei stain blue; granules, neutrophile stain red; granules, basophile stain dark violet; granules, eosinophile brilliant crimson.

Malarial parasites	} blue
Bacteria	
Filaria	

Reuter:¹⁵

Preparation of the solution of polychrome methylene-blue.

To 100 cc. of 1% aqueous solution of methylene-blue—blue med. puriss. (Höchst) add 0.5 gm. Na_2CO_3 . Keep this solution for 2 or 3 days at 40° to 60° C. Filter.

Preparation of the neutral stain.

Without previously neutralizing the polychrome methylene-blue, add to it a saturated aqueous solution of eosin (Höchst). Filter off the precipitate formed, and wash it with distilled water. Then dry it.

Preparation of the staining solution.

Dissolve the dry precipitate in hot absolute alcohol (ethyl), using 0.2 gm. precipitate to 100 cc. alcohol. Filter. Add 2 cc. anilin oil to 100 cc. staining solution. Of this solution add 1 or 2 drops to 1 cc. distilled water (or 30 drops to 20 cc. water.) In this mixture stain fresh films for 20 minutes to $\frac{1}{2}$ hour; older films from 3 to 4 hours. Fix blood-films for 1 hour in a mixture of equal parts of absolute alcohol and ether.

Staining reactions:

Red blood-corpuscles stain pale orange.
Malarial parasites—nuclei, chromatin stains violet; cytoplasm stains blue.

Leishman:¹⁶

Preparation of the neutral stain.

Solution A.—The solution of polychrome methylene-blue. A 1% aqueous solution of methylene-blue med. (Grübler) is made alkaline with 0.5% Na_2CO_3 . This is heated for 12 hours at 65°C., and then allowed to stand for 10 days before use.

Solution B.—A 0.1% aqueous solution of eosin (extra BA Grübler).

Equal parts of Solutions A and B are mixed in an open vessel and allowed to stand for 5 or 6 hours, with occasional stirring. The precipitate formed is collected on a filter, washed with water, dried, and powdered.

The staining solution:

Dissolve 0.1 gm. of the dry precipitate in 100 cc. pure methyl alcohol (Merck "for analysis").

To stain:

Four drops of the solution are poured on the blood-film, and allowed to stain for $\frac{1}{2}$ minute. Without pouring off the stain, 6 drops to 8 drops of distilled water are added and the mixture is allowed to stain for 5 minutes. Wash gently. Put few drops of water on the blood-film for 1 minute. Then dry, and mount.

Staining reactions:

Red blood-corpuscles stain pale pink or greenish.

Leukocytes:

Lymphocytes—nuclei stain dark ruby red; protoplasm stains pale blue.

Mononuclears—nuclei stain ruby red; protoplasm stains pale blue.

Polymorphonuclear neutrophiles—nuclei stain ruby red; granules stain red.

"Coarse-grained eosinophiles"—nuclei stain ruby red; granules stain pale pink.

Basophiles—nuclei stain red; granules stain purplish black.

Blood-platelets stain deep ruby red.

Malarial parasites—nuclei, chromatin portion stains ruby red; cytoplasm stains blue.

Wright:²⁶

Preparation of the neutral stain.

Solution A.—Make a 0.5% aqueous solution of the NaHCO_3 , being careful to bring all of the salt into solution before going on to the next step. Then add 1% of methylene-blue (Grübler's methylene-blue, "Bx," "Koch," or "Ehrlich's Rectified"). Steam this in an Arnold sterilizer for 1 hour after steam is up. Cool.

Solution B.—0.1% aqueous solution of eosin (Grübler, "yellowish, soluble in water").

Add Solution B to Solution A until the mixture becomes purple, a metallic scum forms on the surface, and a finely granular black precipitate appears in suspension. (About 500 cc. of Solution B to 100 cc. of Solution A.) Filter off the precipitate. Do not wash it. Dry.

Preparation of the staining solution.

Make a saturated solution of the precipitate in pure methyl alcohol (0.3 gm. in 100 cc. methyl alcohol). Filter, and add an additional 25% of the original volume of methyl alcohol used. This prevents precipitation of the stain on the film.

Staining: In staining use the blood-films. Cover the film with the stain for 1 minute. Without pouring off the stain, add water drop by drop until the mixture is translucent at the edges, and a yellowish metallic scum forms on the surface. Stain in this diluted stain for 2 to 3 minutes. Wash in distilled water until the film becomes pink. Dry between filter papers.

Staining reactions:

Lymphocytes—nuclei stain dark purplish-blue cytoplasm stains robin's egg.

Large mononuclears—nuclei stain blue; cytoplasm stains pale blue.

Polymorphonuclear neutrophiles—nuclei stain blue; granules stain reddish-lilac.

Eosinophiles—nuclei stain blue; granules stain blue.

Mastzellen—nuclei stain blue to purplish; granules stain dark blue or purple.

Myelocytes—nuclei stain dark blue or lilac; granules stain dark or reddish-lilac.

Blood-platelets stain blue or purplish.

Malarial parasites—nuclei chromatin portion stains lilac-red to a black; cytoplasm stains blue.

SOME REMARKS ON THE ETIOLOGY OF HYPERPLASIA OF THE PHARYNGEAL TONSIL IN THE LIGHT OF RECENT INVESTIGATIONS.*

BY

THOMAS J. HARRIS, M.D.,

of New York City.

Professor Adjunct of Laryngology, New York Postgraduate School and Hospital.

A leading rhinologist recently said: "The contributions to the subject of adenoids in the last two decades have been well nigh inexhaustible, and yet little of value has been advanced that was not contained in William Meyer's original paper." After such a sweeping judgment from one who is intimately acquainted with the entire literature of the subject it seems indeed like presumption to add to this accumulated store, especially as I frankly admit that nothing strictly new will be advanced or claimed by me. Whatever may be held, however, regarding the completeness of our knowledge of the diagnosis and therapy of adenoids, it will be generally conceded that the question of their origin is still almost as much of a closed book as it was in Meyer's time. The causal factors in respect not merely to adenoids, but postnasal catarrh as well, are today receiving and deserving of more and more consideration. The pendulum is on the backward swing. For many years the rhinologist has seen causes of catarrh in every spur and turbinal. Today we are recognizing that these are too often only accidents or possible results and the true cause is remote and out of sight. The medicine of the future will not be chiefly therapeutic but prophylactic. No longer will we content ourselves with relieving results, but in preventing them. The subject of the etiology of adenoids is, on account of its importance, deserving then of further brief consideration.

We propose to consider in the following pages the more important views as to their origin, and try in this way to arrive at some reasonable conclusions.

At the outset we are confronted with the difficulties of obtaining a suitable definition of pharyngeal hyperplasia. The presence normally of a certain amount of lymphatic tissue at the vault of the pharynx as well as in the fauces, at the base of the tongue, on the floor of the nose and in the mouth of the eustachian tubes, has long been demonstrated. Histologically, the adenoid growth in most instances differs in no wise from this normal lymphatic tissue, but it is impossible to say where the one ends and the other begins, aside from the symptoms produced by the growth. The writer first quoted, justly remarks that many healthy pharyngeal tonsils have been scraped away through the overzeal of some too ambitious operator. This normal lymphatic tissue has no constant size. It varies decidedly in different individuals, resembling in this particular its analog, Peyer's patches, in the intestines. That the adenoid growth is then a hyperplasia and not a neoplasm, must be borne constantly in mind.

For many years certain *constitutional factors* have been regarded with favor as predisposing causes.

Heredity seems to play a limited role at least. Various observers have reported the presence of adenoids in children at birth. This is, however, rare. Meyer found them most common after 5 years. Certain cases occur in which one or both parents suffered in *childhood* from adenoids. It is true, however, as Brieger observed, that while many parents with pharyngopathies have descendants suffering from adenoids, an equal number of children with adenoids have parents with all these symptoms lacking. Further, the almost universal presence of catarrh in our climate militates against too sweeping conclusions in this particular.

Tuberculosis.—A certain percentage of adenoid cases

* Candidate's Thesis in American Laryngological Association, presented May, 1903.

show the presence of tubercle bacilli in the growth. The frequency of their occurrence and the significance vary much according to the individual observer. In the last few years several men have busied themselves with this subject. Dieulafoy, in 1895, published his results which were as high as 20%; Pluder and Fisher, of Hamburg, examined 32 cases of adenoid hypertrophy, with 15% showing tubercle bacilli; McBride and Turner,¹ found only 3%. Clinically the latter figure would seem much nearer correct. Certainly it is open to question that all these are cases of primary tuberculosis. Many cases of pulmonary tuberculosis show no tubercle bacilli in the growth.

Syphilis as a common predisposing cause is of little importance except in an indirect way, just as hygiene, diet, etc. Chappell found 36% of adenoids in 2,000 school children. Harrison Allen found 33%. It is probable that a mean between these two extremes is nearest the truth. Syphilis cannot possibly account for such a number of cases.

Scrofula.—For many years the favorite and certainly most plausible theory has been a direct or indirect association with scrofula or struma. Certain symptoms were recognized as peculiar to both, and the immediate deduction was drawn of a cause and effect. In recent years, however, it has been pointed out that many of these symptoms disappear on the removal of the adenoids. A more exact definition too for struma has been demanded. It is true that we are wont to find hyperplasia of the pharyngeal tonsils in blond children with glandular enlargements. We meet it, however, continually when such enlargements are lacking. Meyer has shown that the Hebrew race is especially predisposed to this hyperplasia. Negroes, on the contrary, frequently the subjects of rickets, are singularly free. This latter fact has been explained on the ground of their flat, open nares, and the character of the palatine arch. Further, it is a fact that while we meet adenoid cases with marked glandular enlargements, this is rare, and it is not found in the vast majority of cases. Masini² has made a number of elaborate experiments to account for some of the most striking of these symptoms. He believes in a process of intoxication as a result of the adenoids, due to insufficiency or failure of a particular secretion of the glands. His line of study was directed: 1. To the consideration of the effect of this pharyngeal secretion upon the cardiovascular system. 2. As to insufficient respiration in adenoid cases. 3. As to hypooxygenation of the blood as a result of corpuscular resistance and alteration in these corpuscles. (a) He found arterial pressure as a result of the injection was raised. There was a slowing of the pulse; the ventricular contraction was lessened. (b) Under *respiratory insufficiency* the question of mouth-breathing was considered. By careful experiment he shows that a man can take up only just so much oxygen for change into oxyhemoglobin. When the nose becomes obstructed the system gradually adapts itself to obtaining the necessary amount of air through the mouth. For an adult, 100 cc. of oxygen is the limit for each respiration, or 516,500 cc. in 24 hours. Now it is demonstrable that a person with nasal stenosis, breathing through the mouth does not take in this amount, although a condition of hypooxygenation of the blood is continually in progress, due to permanent incapacity to introduce air under normal physiologic conditions. The vital capacity (23,220 cc.) of adults is not found proportionately in children with adenoids, due as he shows to insufficient fullness of the thorax and poor development in the muscles of the respiration. By ingeniously devised instruments he registered the expansion of the thorax and the vital capacity in (1) children with adenoids; (2) children with nasal stenosis due to other causes; (3) healthy children. In the first class he found inspiration and expiration were less full than in the healthy children, although as a result of frequency of respiration, the same quantity of air enters the

lungs in the same unit of time. The accompanying tracings showed it is not absolutely impossible to obtain the necessary amount of air by the mouth. Deficient respiration by the mouth is not due to the mouth, but to poor respiratory muscle action. The half-open mouth is intended to prevent too large a quantity of air going in. The lips act as the alæ of the nose and produce the same effect. The great difference in children with adenoids is in the vital capacity. In the second class of cases the vital capacity is fuller, the color is better, and the expansion of the thorax is larger. Respiratory insufficiency, however, is not the principal cause of cachexia according to him, but rather blood changes due to the presence of faulty gland secretion just mentioned. The hemoglobin is less firmly fixed in the red corpuscles and attains its proper color more slowly. He found fewer red corpuscles by a fifth. The presence of macrocytes is noticeable. The resisting power of the red corpuscles is reduced. Poikilocytes representing necrobiotic processes abound. The leukocytes are increased, with many lymphocytes. Such in a few words are Masini's conclusions which are here given as worthy of consideration.

While we are forced to revise our former views as to the relation of scrofula and pharyngeal hyperplasia, it is true, however, that some diathetic condition seems to be at the bottom of a large number of cases. Bosworth,³ with his usual clearness of observation and judgment, has fully stated this many years ago, and his position is still deserving of recognition. There is what he calls a lymphatic habit, or, quoting Potain, "a lymphatismus." This means a particular susceptibility in children for lymphatic tissue to take on inflammation and so increase in size. This peculiar property of lymphatic tissue is further borne out by the marked tendency now well recognized, of the adenoid vegetations to recur after operation. Up to the time of Hopkin's paper, written some 10 years ago, it was generally held that such recurrence did not take place. We know now that it is by no means uncommon. Recently Görke⁴ has discussed the subject in an exhaustive manner, especially from the histologic standpoint. After stating the two commonly held explanations for the recurrence, viz., malignancy and imperfect operation, and giving convincing proof that neither of these reasons can be the cause in the majority of cases, he shows that the structure of the growth resembles in the main that of the ordinary pharyngeal hyperplasia, but differs in this particular, "that a sharp division of the different layers is not possible." This lymphatismus is not a pathologic, but a normal process; it is not scrofula or struma, but carried a step further, it may become so. We shall consider in a few moments the occasion for this physiologic process. We know this tendency to lymphatic enlargement disappears as adult life is reached. Recognizing this property of infant lymphoid tissue to take on enlargement, it follows that any distinct and persisting cause is liable to produce this effect. Mulford,⁵ as a result of observation of many cases and of two cases reported, believes some blood diathesis is always at work, often allied in effect to that of uric acid in the blood, which if not cured will render invalid any operative measures on the throat. Haig, in his book, "Uric Acid in the Causation of Diseases," refers to a communication from Dr. Mackie, of Nottingham, which may be of interest in that there is noted an almost constant connection between catarrhal conditions of the nose and throat, adenoids, etc., and the uric acid diathesis. Mackie has read two papers on the subject before the Medical Society of Nottingham, and he says in a letter to Haig that he has hardly ever seen a case of adenoids, say in a child, except there is arthritic or migrainous parentage, and it is obvious that such conditions may quite easily occur from recurrent uratic irritations. As a further illustration of a remote cause acting on normal lymphatic tissue, Kyle⁶ states "he has frequently met enlargement of the pharyngeal tonsil, which is not a hyperplasia at all,

but a turgescence and cyanotic congestion with watery infiltration of the nasal and postnasal space." This is a result of intestinal irritations, such as constipation, and will disappear at once under appropriate treatment of the bowels. The writer is convinced he has more than once met such cases in which no inquiry was made into the condition of the gastrointestinal canal and in which at operation little, save normal tissue, was discoverable. Climate has been often advanced as an important factor in a causative way, also the dust of cities, but without sufficient reason, save as all unhealthy conditions serve to irritate tissue easily irritated. The distribution of the disease is uniformly widespread, although observers have noted its relative infrequency in savage life.

Inflammation.—Whatever may be correct regarding the importance of a diathetic cause, that of inflammation is generally conceded. Catching cold, whatever that is, is characterized by acute inflammatory swelling of the pharyngeal tonsil. This leads without question to chronic enlargements. Some writers, notably Greville MacDonald¹ have sought to discover a similar result from pronounced nasal stenosis or obstruction. MacDonald states that, "In a large proportion of cases we find at the same time obstruction of the nasal fossas in one form or another. The commonest of these is engorgement of the erectile tissue which in some cases has advanced to actual hyperplasia of the inferior spongy body. Next in point of frequency we find a septum variously deflected and hypertrophied, sufficiently to cause considerable stenosis of one or both sides. So frequently does some other source of obstruction coexist together with the postnasal adenoids, that it is exceptional to find respiration completely restored by removing the adenoids, some further treatment of the anterior region being demanded before the patient will instinctively keep the mouth closed." The total number of MacDonald's cases however was 154. My experience covering a large clinical service for the last 10 years is decidedly at variance with MacDonald's. Hypertrophies of the turbinals are rare, while septal deformities of any considerable degree have scarcely ever been met. Nor has it been my experience to find the majority of patients requiring any postoperative treatment. The most common nasal condition present was a boggy swollen condition of the inferior turbinals, which rapidly subsided after the removal of the adenoid growth. Repeatedly cases have been referred to me in which all previous treatment directed to the nose alone had failed to relieve nasal stenosis, but in which the obstruction at once disappeared after adenotomy. In many cases, however, no pronounced nasal obstruction is discoverable. To my mind the views commonly held that the nasal condition is a result of postnasal obstruction is the much more natural one and in the majority of cases represents the proper relation of cause and effect. The infectious diseases, however, scarlet fever, diphtheria, typhoid, etc., have been generally regarded as common inflammatory causes. That the hyperplasia develops after the attack seems beyond cavil. I have failed, however, to find any series of cases reported in which a previous examination, before the sickness, had been made and the presence of hyperplasia definitely excluded. It seems in many cases the hyperplasia was already present and the inflammation acted as the diathesis already referred to, to excite its further growth.

The most encouraging and promising grounds for explaining these clinical phenomena have been along the line of investigation and study of the tonsil function. Many observers have busied themselves in this direction and certain well-accepted facts have been secured. It is now held by most writers that the tonsil, and here we include the faucial tonsil as well, has a definite function though there is a difference of opinion as to how important this is. Harrison Allen many years ago, called attention to the probability of its sharing as a blood-making organ. How largely this is developed is questionable. That

such is the case seems reasonable when we consider the richness of the blood in lymphocytes in childhood, and their gradual disappearance in adult life. Stöhr has shown a constant migration of leukocytes out of the tonsils to the surface. Metchnikoff definitely proved the function of phagocytosis in the tonsil epithelium. Numerous careful observers have showed the intimate relation of tonsillitis and articular rheumatism in many instances. Recognizing this diapedesis of the lymphocytes, we have to inquire: (1) What effect, if any, does the hyperplasia have on their activity? (2) What does the microscope show to point to an inflammatory origin? (3) What is the end and aim of such diapedesis? Brieger² has exhaustively treated this question in a recent number of Fraenkel's Archives. Brieger and Wex found certain inflammatory changes in the tonsil as follows: (a) In spots the columnar epithelium is replaced by squamous. This occurs independent of the size of the tonsils and of inflammatory changes in the propria. It does not necessarily depend on inflammation, as Wex saw it in a child 5 days old. Diapedesis contrary to the assertion of Hill, goes on as in the normal tonsil though less actively in the squamous areas. Collections of leukocytes were seen beneath the surface resembling a picture of small-cell infiltration. *Lymphocytes* predominate in the epithelium as in the propria. Polynuclear leukocytes are also found in the propria occasionally. Some areas contain leukocytes alone. This does not occur often enough to suggest acute inflammation. The difference in the number of leukocytes in the hyperplastic tissue and in the inflammatory process, is very noticeable. (b) The lymphatic structure is unchanged. The follicles in older children may fail or appear as sharply defined round-cell collections with clear nuclei. (c) Bloodvessel changes are seen which point to inflammatory processes, such as swelling in the endothelium or even complete obliteration, also at times hyaline degeneration. (d) The reticulum shows no change. Now all these inflammatory changes are distinguished by not attacking all layers uniformly. They are found in the hyperplasia of leukemia and are lacking altogether in large adenoid vegetations. This in Brieger's opinion can mean only accidental occurrence taking place on one or several definite occasions. If such hyperplasia takes place without necessary inflammatory changes, attended by undisturbed diapedesis, what deduction has to be drawn as to its origin? It would clearly point to some function the tonsil discharges, which can better be discharged by an increase in size. The phagocytic power of the tonsillar mucous membrane is well established. Equally recognized is the peculiar susceptibility in childhood to infectious diseases. This susceptibility, however, is entirely out of proportion to the constant exposure and the number of bacteria of a virulent nature in the air. Now the lining membrane of the nose possesses a certain protecting power against bacteria. The pharyngeal tonsil is decidedly freer from bacteria than the anterior part of the nose. The ciliated epithelium of the nose assists in affecting this result. This power is, however, limited, and depends on circumstances. In a child with hyperplastic tonsil when mechanical cleansing of the nose through sneezing is impossible, the tonsil is covered with numerous bacteria. Further, as shown by St. Clair Thompson and Hewlett, while usually removed from the nose in a short time, they can occasionally be found there after several hours. They are under normal conditions avirulent, but disturb this normal protecting medium and at once they become virulent. The nose is then not sufficient in its protecting power. What of the tonsils themselves? Their surface presents only apparent defects in its continuity; in reality it is unbroken. The exits in the lacunæ are at once filled with the cement substance of the epithelium. The bacteria do not penetrate to the interior. Experiments to test this resisting power have been carried on by Hendersohn³ and Goodale, independently, which

would seem to discredit the above assertion of Brieger. They employed various coloring powders dusted on the tonsils. Hendersohn found (1) 15 minutes after the application of the powder, fine coal particles in the tonsil inside the epithelium. (2) The longer they remain the deeper they penetrate. (3) They are partially in the cells and partially in the lacunæ. If these experiments were fully established, the tonsillar resisting function would certainly be proved useless. Brieger, however, has carried out some similar investigations which do not at all correspond with these. In certain spots a small amount of coloring matter was found in the propria, but no collections. It is further true that even granted bacteria do penetrate, it is rare in proportion to the innumerable exposures. It is further open to serious doubt whether any such experiments correspond to the actual condition in life. This protection admitted, and it seems reasonable to recognize that it does exist, where in the tonsil does it reside? Most clearly it is in some way associated with the constant, unceasing outward flow of the lymphocytes. The statement that it ceases in certain diseases, as in leukemia, is not correct. It is lacking in spots, but elsewhere it is found undisturbed. It even goes on in pathologic conditions of the tonsil itself, as in tuberculosis. Brieger has further shown that the lymphocytes in themselves are not bactericidal. This must mean that the property resides in the medium in which they reach the surface. This is not capable of demonstration, because the fluid cannot be recovered. We can, however, reason by analogy from the antiseptic quality of the fluid sneezed from the nose. It is possible, too, that in the rapid disappearance of the leukocytes on reaching the surface, this quality is evolved. It is at once apparent that wherever the quality resides, the call for greater activity, which is being continually sent out in childhood, means increased size of the organ producing it, namely, the tonsil itself, and we arrive thus at a reasonable explanation of the hyperplasia. Nor must the seeming relation to the recent view of the nature of inflammation be omitted, viz., that the piling up of numerous small, round cells is really a natural method of erecting a wall against the invasion of the bacteria. If there is truth in this, we can easily see that the two theories as to the origin of hyperplasia are not so far apart.

As regards this and as to many other points in connection with this interesting subject, much work still remains to be done. It is not claimed that the views set forth will explain every possible query. For instance, why, in a family of several children one should have adenoid vegetations and the others be entirely free? It may be that in this case, as in that of different families, the resisting power to excessive lymphatic development (lymphatismus) is less strong through certain embryonic influences in the child affected than in the others. Just as in such a family, one will be weakly while the others are all strong.

Two facts, however, are beyond dispute. 1. The peculiar susceptibility in childhood to infectious diseases. 2. The mode of invasion is by the upper respiratory tract.

Conclusions.—As corollary to these we venture to add as a result of this study, the following conclusions: 1. The pharyngeal tonsil possesses a distinct function or functions. 2. This function is of the nature of a defense against the entrance of bacteria and consists in a certain irrigation of the tonsil surface by a lymph stream loaded with lymphocytes. 3. This protection function carries with it the inherent qualities of the tonsil to enlarge on the slightest irritation for the affording of further power of defense. 4. This inherent tendency of the tonsil to enlarge is further seen in the frequent recurrence of the tonsil after removal. 5. Strictly speaking then, in the great majority of cases such enlargements are not a pathologic, but a physiologic process.

PERCENTAGE SOLUTIONS, WITH REFERENCE TO THE METRIC SYSTEM.

BY

JOSEPH W. ENGLAND,

of Philadelphia.

Considerable confusion exists both in medical and pharmaceutic circles regarding the exact nature of percentage solutions in prescription work. The difficulty seems to be due, first, to a failure to make a sharp distinction between percentage by weight, and percentage by volume, and, second, to the lack of authoritative rules of practice.

Percentage by weight, and percentage by volume, are by no means identical. In the former, the proportions of ingredients are all by weight; in the latter, the active substances are by weight, and the solvents by volume. When the term percentage alone is used, percentage by weight is understood; when percentage by volume is meant, it is (or should be) always so expressed.

Regarding percentage, or percentage by weight: The mixing of different weights of different solids, or of different liquids, to obtain certain percentage mixtures, presents no especial difficulties. It is simply a matter of relative proportions. But the determination of the amount of a solid or solids necessary to dissolve in a liquid to make a certain percentage solution is not so easy, especially when it is desired to find the quantity of a solid necessary for a fluidounce, pint, etc., of the solution.

The weight of a fluidounce of water—the universal solvent of solids—at the ordinary temperature is 455.7 grains, and of each pint 7,291 grains, and *not* 480 grains and 7,680 grains, respectively, as often assumed.

In the making, for example, of a fluidounce of a 4% solution of cocaine hydrochlorate in water, several methods may be followed. One method is to assume that the weight of a fluidounce of water is 96%, and then ascertain the 4% of alkaloidal salt by simple proportion as follows:

$$96 : 4 :: 455.7 : 18.9$$

Thus, 18.9 grains of the salt dissolved in 1 fluidounce of water will give a 4% solution, slightly more than a fluidounce (by reason of the increase in volume resulting from the solution of the salt).

Another method is to assume that 455.7 is 100%, and then ascertain the 4% of alkaloidal salt by proportion as follows:

$$100 : 4 :: 455.7 : 18.2$$

Thus, 18.2 grains of the salt dissolved in sufficient water to make the solution weigh 455.7 grains, yields a 4% solution. The volume of the solution, however, is slightly less than a fluidounce.

Solids on solution increase the volume of the solution according to the nature of the solid dissolved, and to obtain exactly a fluidounce or a pint of a certain percentage solution of a compound, correction must be made for the relative expansion in volume of each solid on solution.

Practically, the best method and the one very generally followed by pharmacists is to take the weight in grains of a fluidounce or a pint of water as the basis of calculation, multiply this by the percentage desired, and dissolve the salt in sufficient water to measure one fluidounce or one pint, as the case may be. Scientifically, this

procedure is not exact; practically, it answers the purpose.

By this method one fluidounce of water would require 18.2 grains of cocain hydrochlorate to make a 4% solution, and if we wished to make a 1-1,000, 1-1,500, or 1-2,000 solution of mercuric chlorid, we would divide 7,291 by 1,000, 1,500, or 2,000, as the case may be, to ascertain the number of grains needed for each pint, and then dissolve in sufficient water to make the pint. With solutions of carbolic acid (1-20, 1-40, or 1-60, etc.), we would divide 7,291 by 20, 40, and 60, respectively, and then dissolve the necessary number of grains of acid in sufficient water to make the final volume measure one pint. Gallon quantities would require, of course, eight times the quantities necessary for pints.

When a liquid other than water is used as the solvent, the weight in grains of a fluidounce or pint must first be obtained by multiplying 455.7 or 7,291 by the specific gravity of the liquid, and with this factor the quantity of solid necessary can be ascertained. If the specific gravity of a liquid be 0.820, then 455.7 multiplied by the gravity will give its weight in grains. Or, if instead of alcohol (with its gravity of 0.820), ether, with a gravity of 0.725, or glycerin, with a gravity of 1.25, or chloroform with a gravity of 1.485 be employed, a similar course of action can be followed. As a matter of fact, however, these solvents are very rarely used in percentage solutions in prescription writing.

Several months ago I called the attention of the Revision Committee of the U. S. Pharmacopeia to the question of percentage solutions in prescription work, and urged that there be given in the forthcoming edition of the national standard, authoritative rules of procedure for determining percentage, and the question is being considered by the committee.

It would be a much simpler procedure, however, if physicians generally would write for percentage solutions in the metric system of weights and measures. This system is essentially a percentage system, and calculations can be made most easily with it. Instead of using 18 grains of cocain hydrochlorate in a fluidounce of water (to make a 4% solution), how much simpler it would be to use 1 gm. in 25 cc., or in place of 7.3 grains of mercuric chlorid in a pint of water (to make a 1-1,000 solution), to use 1 gm. in 1,000 cc., or instead of dissolving 365 grains of carbolic acid in a pint of water (to make a 1-20 solution), to use 50 gm. in 1,000 cc.

If this were done the real merits of the metric system would become much more apparent than at present, and its use in American medical practice much more general. The adoption of the metric system by the Anglo-Saxon has been handicapped by the employment of a needless multiplicity of terms and an unnecessary use of scientifically exact equivalents.

The United States Government adopted, a century ago, its decimal or metric system of money—with its mills, dimes, cents, and dollars—but popular usage, in writing, at least, has reduced the terms in number to dollars and cents.

Similarly, if the metric system of weights and measures for the writing of prescriptions is ever going to be generally employed it will only be after it has been decided to use as few terms as possible. For prescription work there is no need of more than three terms for solids and one for liquids, and one or two for linear measurements (the centimeter [cm.], and possibly the meter).

If the German practice of weighing both solids and liquids were to obtain in this country, weights only would be necessary, but it is most improbable that the Anglo-Saxon will weigh liquids. With him it is, always has been, and probably always will be "solids by weight and liquids by measure."

The three terms necessary for metric weights are the gram (gm., or 1.), the centigram (cg., or 0.01), and the

milligram (mg., or 0.001); for volumetric measure, one term only need be used—the cubic centimeter (cc.).

Objection has been made to the use of the metric system in prescription-writing on the ground that the employment of the metric decimal point or dividing line opens the door to very serious possibilities of error in prescribing, errors of one point resulting in ten times too much of a substance being given or ten times too little. These possibilities could be obviated, if desired, by writing the terms gm., cg., mg., or cc. in place of using the period or dividing line. This would be an improvement also, so far as the number of terms is concerned, over the use of the terms grain, dram, ounce, pound, minim, fluidram, fluidounce, or pint.

In speaking or writing metrically, the quantities of solid drugs for which the doses are 1 grain or less, could be expressed in milligrams; those for which doses are less than 15 grains, in centigrams, and larger doses in grams. It would also greatly simplify calculations if the usual custom of ordering six or eight or multiple doses in prescriptions for internal use, was entirely abolished, and in its place five or ten or multiple doses were prescribed. By this means the quantities of ingredients to be used could be more readily made into even amounts.

When the metric system was first proposed for American medical practice, the mistake was made of giving absolutely exact equivalents of the metric weights and measures in the old form of weights and measures, of carrying the equivalents out to three or four decimal places. Such a procedure fell by its own weight. No one would prescribe, for example, 10-grain doses of potassium iodid in its exact metric equivalent of 0.648 gm., and multiply this by the number of doses required, nor 20-grain doses of potassium bromid in its exact metrical equivalent of 1.296 gm., nor $\frac{1}{2}$ -grain doses of potassium cyanid in its exact metrical equivalent of 0.0081 gm. Life was too short, and the use of scientifically exact equivalents "died a bornin'."

The unwisdom of such a method of introduction is obvious. The only right way to use the metric system is to think in metric terms. Not to think in one system and then laboriously translate into another. If medicine was an exact science, or, expressing the thought differently, if drugs and human beings were both of exact and uniform composition, there might be reason in requiring punctiliously exact dosage; but since both are very variable factors, and since the dose of a drug is "enough to produce physiologic results," it follows that doses must vary within rather wide limits relatively. Practically, what therapeutic difference does it make whether one gives 0.65 gm. (10.03 gr.) or 0.648 gm. (10 gr.) of potassium iodid; 1.25 gm. (19.29 gr.), or 1.296 gm. (20 gr.) of potassium bromid; or 0.01 gm. ($\frac{1}{2}$ gr.) or 0.0081 gm. ($\frac{1}{2}$ gr.) of potassium cyanid?

The differences are immaterial and far less than obtain, for example, with the common household spoons that are generally used to measure doses for the sick. Some of these utensils hold 25% more liquid than they are assumed to hold.

It is only by thinking, in terms of the metric system, that its beautiful simplicity becomes most evident, but this cannot be done in prescription work until there is fixed in the mind reasonably exact equivalents in seven numbers as possible of the usual doses, as basic principles, and then ordering quantities of five or ten doses or multiples.

It will be of value, in this connection, to know that comprehensive investigations have shown that the usual teaspoon holds 5 cc. of liquid, the dessertspoon 10 cc., and the tablespoon 15 cc. A minim is practically 0.06 cc.; a grain is practically 0.065 gm.

If the metric system is ever going to find common usage among the English speaking people, multiplicity of terms must be avoided and a clear simple and rational method of use must be followed, just as has been done with the monetary system of the United States.

SEASICKNESS : ETIOLOGY AND PROPHYLAXIS

BY

E. KIRKLAND SHELMEKDINE, M.D.,

of Philadelphia.

Surgeon to Philadelphia Rapid Transit Company.

From time immemorial those who travel in ships have suffered from *mal de mer*. To appreciate thoroughly the misery accompanying this malady, one has only to experience the agony of being a victim of Neptune's wrath; oft-repeated voyages are not always a preventive against this complaint; there are cases on record of sea captains who become sick at the beginning of each ocean trip, the longer the interval between sailings the more apt are they to suffer from qualms of the stomach; on the other hand, some people are never sick; and again, there are others who will be sick one trip, and the next, with the ocean equally rough, will not be at all inconvenienced. There must be some factor, some state of the body which renders an individual susceptible to the waves and not the mere motion of the ship itself which causes nausea.

From observations of fellow passengers made during 6 ocean trips, one of 30 days' duration, I draw the following conclusion: Seasickness is the result of 3 factors, acting together or independently—mechanical, mental, and the irritating influence of the bile in the stomach.

Mechanical.—To maintain the equilibrium on board ship requires a constant change in the angle described by the long axis of the body and the deck of the vessel. This constant change of position necessitates action on the part of antagonistic muscles necessary for the maintenance of the center of gravity in the upright body; this action is voluntary, or not according to whether the individual has accustomed himself to the motion of the ship or not. When in nautical language, the "land-lubber" has acquired his "sea-legs," the alternate contraction and relaxation of the muscles governing the erect position are involuntary, the balancing of the body requires no more direct effort of the will than is necessary on terra firma. On the other hand, lack of the abnegation of the mind in the consciousness of a changing base, is responsible for the extreme gait and frequent overbalancing on the part of the novice. Not having learned just how much muscular effort is essential to overcome the tendency to fall, there is too much muscular contraction, and the individual throws himself too far to the opposite side, immediately there is another muscular contraction antagonistic in character to the last, an effort to regain the perpendicular. These alternate muscular efforts may be repeated several times in succession before the requisite tension necessary for the upright position is acquired. Indeed, on shipboard it is a source of amusement to watch the oscillating efforts of those who have not acquired their "sea-legs."

Muscular sense and dexterity are easily lost through lack of practice; for example, an expert tennis player, after several years' absence from the courts, will suffer defeat from players who are his inferiors when in practice. The uninitiated and those who have forgotten how to balance on board ship can be compared to children learning to draw. Here, also, the muscular system, which is not necessary for the act of drawing, is also in a state of tension; the child's face works while the stroke is being made showing that the nervous force emanating from the brain centers, is also causing other muscles to contract; there is apparently an excess of stimuli overflowing into groups of muscles not necessary for the consummation of the act of drawing. Observations of the tottering victims show that there are spasmodic contractions of the whole body, especially when there is fear that overbalancing will take place. Not only do the muscles of the trunk and legs undergo excessive activity, but the diaphragm is also elevated by the muscles of the chest during inspiration; in other

words, there is a "catching of the breath," an act which is present in all individuals who try to "catch themselves from falling."

Bile.—Many go on board ship in a bilious condition, the bile ducts as well as the gallbladder being overfilled with bile. From the spasmodic muscular contractions of the abdominal muscles pressing on the liver and gallbladder and the general shaking up people get on shipboard, the bile is forced out into an intestinal tract which is possibly suffering from constipation. The spasmodic elevation of the diaphragm causes a negative pressure in the stomach, and the abdominal pressure accompanied by constipation and possibly slight reversed intestinal peristalsis cause the bile to flow in the direction of least resistance. These combined forces are sufficient to overcome the resistance of the pylorus, and the bile gains entrance to the stomach, often in enormous quantities. During one experience of seasickness through which I passed, I vomited in the course of 3 days in the neighborhood of a pint of bile, and what is more to the point, when the bile ceased to come up, the nausea disappeared.

Mental.—The nervous element which is also a part of seasickness, prevents that speedy confidence in one's ability to navigate, and hinders that loss of consciousness of voluntary effort, the absence of which would enable one to acquire a freedom of movement and relieve the muscular tension so that the rise and fall of the vessel would be met by an involuntary action of the human guy-ropes pulling the trunk into an upright position and the excessive over-production of energy would be reduced to the minimum force required.

To summarize: In seasickness there is considerable bile in the vomitus. In ordinary attacks of biliousness there is bile present in the stomach, and in bilious headaches there is always a feeling of nausea present. Bile is a foreign body in the stomach, it is repugnant to the mucous membrane, and in sufficient quantities excites vomiting, which is nature's effort to get rid of undesirable material.

There are unnatural, spasmodic, muscular contractions in seasickness, excessive spasmodic elevations of the chest and diaphragm, and compression of the contents of the abdomen all causing a negative pressure in the stomach.

Nervousness hinders the acquirement of proper balancing powers.

Observation of a number of individuals has made prominent the fact that in the vast majority of cases when the bile ceases to be vomited the seasickness disappears.

Treatment.—Prevention of seasickness is easier than cure. The prophylactic treatment is simple, and in the few cases in which it has been tried, was marked with decided success. For example, in 1 case, the patient, Miss S., on 2 previous trips had to be carried ashore, so completely prostrated was she from the effects of seasickness. On the third trip she was only slightly nauseated, and then only for a day and a half. She did not vomit, and she missed but one meal. The treatment in her case did not start as soon as it should have, and she did not have the full benefit of a prolonged cleaning out; medicine was taken 3 days before sailing.

Treatment should start 10 days before sailing. Podophyllin 3 mg. ($\frac{1}{20}$ gr.) 4 times daily. Third, sixth, and the day before sailing, give calomel .13 gm. (2 grs.) in divided doses. The night before sailing, a bottle of magnesium citrate should be given. Five days before sailing give sodium bromid .32 gm. (5 grs.) twice daily, and continue this until the patient has acquired "sea-legs." On board ship great care must be taken to keep the bowels in a loose condition until all danger of nausea has passed away. According to the individual the doses may have to be increased or diminished. The main object is to cleanse the bowels thoroughly and thus get rid of as much bile as possible. In many cases this

treatment will prevent seasickness and if a person becomes sick who has followed this method, he will have a very light case and will not suffer so much as he would have suffered had he gone aboard without having had a good cleaning out.

The individual who goes on board in a bilious state has plenty of excitement ahead, for it is almost impossible to administer medicines by the mouth owing to the irritability of the stomach. When medicine can be retained, calomel is the sheet-anchor of faith and should be given in large doses followed by a stiff saline. Bromids should also be given if they will stay down. For nausea, champagne is the best, but in some cases lemon juice and cracked ice have a very soothing effect. In all cases the bile must be worked off either through the upper or lower end of the intestinal canal; and sad for the victim is the fact that most have to experience the disagreeable sensation of frequent periodic evacuations through the oral cavity. In cases in which vomiting is so persistent that nothing will stay down, benefit may be derived by washing out the stomach and lower bowel. Strapping the chest with adhesive plaster so as to restrict the expansion will tend to quiet an irritable nervous stomach. When possible, seaskick persons should be placed in their steamer chairs on deck where there is plenty of fresh air. A very simple rule to learn for acquiring "sea-legs" is as follows: When the ship rises, do not make yourself stiff and hold back in nervous fear, but rise with the deck, endeavoring, if possible, to go a little farther and higher than the excursion of the deck would have taken you. On the other hand, when the deck sinks do not hold back but accept the situation gracefully and incline your body with as much freedom of movement as possible. It is the resistance and the muscular rigidity which cause much of the trouble, and one should appreciate early the fact that the erect position on a rolling deck is brought about by a series of graduated contractions and relaxations of the muscles concerned in maintaining the perpendicular, and not by a series of jerks which are simply stubborn antagonistic muscular movements. The swaying of the body, therefore, should be easy, a rising and falling synchronous with the movement of the ship, not a series of jerks but an involuntary act. *Sea-legs and seasickness are incompatible.*

Seasickness will be of short duration in an individual whose liver and gallbladder are comparatively free from bile.

Prejudiced against Ambidexterity.—"Professor Lombroso has a curious prejudice against ambidexterity," says *Amateur Work*. "In last month's *North American Review* he gives the results of his observations on left-handed and left-sided people. They are of such a character to make people hesitate even to stretch out the left hand, and it is small consolation for him to make the closing qualification: 'I do not dream of saying that all left-handed people are wicked, but that left-handedness, united to many other traits, may contribute to form one of the worst characters among species.' . . . The professor finds that among 1,000 soldiers and operatives, the proportion of left-handed people is 4% among the men, and 5% and 8% among the women. Among criminals the quota of left-handed was found more than tripled in men and more than quintupled among women."

Better Tenements in New York.—According to the report of Commissioner Robert W. De Forrest, the most interesting change brought about in the department was that evidenced in the "New Building Bureau," where it was shown that in past years 24,000 tenements were approved without correction. Only 527 were passed without alteration during the last year. This shows a decided improvement in tenement houses. Where formerly inspectors were employed to cover certain territory, and told to daily visit all new buildings in that section, now a record of every tenement in the course of erection in Manhattan is kept, and at any hour, information as to the stage of its erection can be obtained. Inspectors are only instructed to visit such places at the times when their presence is required. This has cut down the roll from 60 inspectors to a division, to 8. Under the present regime a permit to build cannot be obtained until the plans have been approved by the plan bureau of the Tenement House Department. Records of the plans are kept, and these are referred to regularly by the inspectors.

SPECIAL ARTICLES

THE MORBID ANATOMY AND HISTOLOGY OF PULMONARY TUBERCULOSIS IN RELATION TO ITS GENERAL PATHOLOGY AND CLINICAL MANIFESTATIONS.

BY

G. SIMS WOODHEAD, M.A. (CANTAB.), M.D. (EDIN.),
Professor of Pathology in the University of Cambridge, England.

Ladies and Gentlemen:—When the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis did me the honor to invite me to give one of this series of lectures, I felt that I had little time in which to prepare any lecture worthy of the occasion. I was just in the midst of the work of our term, and as I had to start for your shores as soon as the term ended, I knew that until I got onto the Atlantic (whose vagaries at this time of the year have to be reckoned with) I should be able to give but little time or attention to the thinking out of the details of my address.

The opportunity of visiting your great country thus presented to me was, however, so tempting and the prospect of meeting my many valued friends on this side so attractive that I determined to give you the results of some of my own work on the relation of the morbid anatomy and histology of phthisis to its general pathology and clinical manifestations. I was all the more tempted to follow this line of thought from the fact that in recent years the pessimistic views of the physician—based on the pessimistic foundation laid by the earlier pathologists—though gradually giving way before the evidence afforded by more recent research, are hard to scotch and still more difficult to kill. It will, of course, be understood that the advancing and advanced lesions found in cases of pulmonary tuberculosis that had succumbed could not but prove fatal. The presence of Virchow's caseous tubercle in all its fearful and destructive simplicity seemed to leave no hope for the recovery of any patient affected; and what the pathologist found one day, the physician accepted the next. It was perhaps natural that this should be the case, but the evil wrought by this pessimism was incalculable, and I think that most of those of you here tonight, who have given even a small amount of attention to the subject will agree with me that this view as to the incurability of tuberculosis had more influence than any other single factor with which we are at present acquainted, in interfering with the successful treatment of a disease that should, I venture to say, now be looked upon as among the most curable—when taken early enough, treated under proper conditions, and for a sufficiently long period.

If modern pathology had been responsible for nothing beyond the effect that its findings have had on our ideas concerning the course of the tuberculous processes, especially in the lung, it would have more than justified its claim to be one of the most important, if not the most important, of all the sciences ancillary to medicine.

I am here to speak as a pathologist, and it is possible, nay, even probable, that some of you may be of opinion that I claim too much for my subject; but of this I am convinced—that the more closely the pathology (including morbid anatomy and histology as read in the light of recent bacteriologic discoveries) of tuberculosis is studied in the cases that come under the observation of your physicians, the greater will be the influence of the work ultimately done in this institute. The cure of the individual must, naturally, be the most pressing and important claim on all those engaging in this work, but it must be remembered that there are far wider reaching questions behind and beyond this—the early detection of the disease, if treatment is to be most successful; and the prevention of the disease, if the community is to derive the greatest benefit from the warfare now being carried on; and these must be worked out, not in the ward merely, but also in the side-room and in the laboratory.

I have said that it is only during recent years that much has been heard of the curability of pulmonary tuberculosis, but it must be borne in mind that after the first shock produced by the observations recorded by Rokitsanski and by Virchow had

lost some of its force, a number of observers drew attention to the fact that in the lungs of old people who had succumbed to diseases other than those of tuberculous origin there could often be found local apical thickening of the pleura or, still more frequently, deeply pigmented irregular scars which were evidently the result of some considerable loss of tissue at an early period of life. My attention having been drawn to this fact, I took the opportunity, after I had been appointed pathologist to the Edinburgh Royal Infirmary, to make a careful search for evidence of what I might speak of as healed tuberculous lesions, and I found that in old people such evidence was to be found in at least one out of every three who came to the post-mortem table. Nay, more, I soon became firmly convinced that even in those cases that succumbed to tuberculous disease there was usually more or less marked evidence of a sturdy war waged by the tissues against the invading tuberculous process, and that in most cases the tissues failed in their endeavor to check the advancing process simply because they were placed under disadvantageous conditions, not as the result of the action of the specific *materies morbi*, but as the result of interference with their nutrition. The cod-liver oil treatment, so long the most successful of all, had its foundation in the belief that this substance served some special nutrient or therapeutic purpose, as a result of which the tissues were strengthened and were thus enabled to resist the attacks of the disease-producing factor; while the present day treatment of tuberculosis is founded on a similar belief that fresh air, good food, efficient excretion of waste products, rest (opportunity for building up the tissues, food that will supply energy with least draft on the tissues), will enable these tissues to withstand the attacks of the tubercle bacillus in the first place; to kill it in the second, or at any rate to render it harmless; and finally, to assist in the removal not only of the bacillus, but of the dead or degenerated tissue in which it had managed to effect a lodgement.

It is perhaps superfluous at this stage to show slides of the tubercle bacillus, but some few of you may not have seen these microbes—low vegetable parasites—so fully studied by Robert Koch in his epoch-making work sent out from the Royal and Imperial Institute of Public Health in Berlin. (A series of slides illustrating the form and relative size of the tubercle bacilli as found in experimentally produced tuberculosis, in the tuberculosis of the human subject, and in phthisical sputa was then thrown on the screen.) For some time after the appearance of Koch's wonderfully lucid and convincing paper a certain number of sceptics—perfectly justifiably, no doubt, on account of the extreme novelty of the ideas so promulgated—attempted to throw doubt first on the accuracy of the observations and then on the reliability of his conclusions, but it may now be fairly claimed that Koch's work has, in the main, withstood the attacks even of the ablest of his critics. There seems to be no manner of doubt that we may accept Koch's tubercle bacillus as the *causa causans* of tuberculosis. Here, however, let me put you on your guard, as I guard myself, against a mistake into which it is very easy to fall, *i. e.*, that because a tubercle bacillus comes near, or even into contact with the human or brute body, an attack of tuberculosis necessarily results. This bacillus must make its way not merely onto a free surface, but into the tissues of the body, before it can do any harm; nay, more, it seems that, in the human body at any rate, the tissues must be damaged or weakened and a special mode of entrance into these damaged tissues must be prepared for the tubercle bacillus before it can work its dire effects. During the course of my work my hands have for weeks, months, or even years, been almost daily soiled with tubercle bacilli; I have no doubt that I have swallowed many, and that some have made their way into my respiratory tract; but none of these have done me much, if any, harm, because while I have been working with them I have carefully protected any cuts on my hands and have refrained from working when I have been run down in any way, and especially when I have been suffering from any catarrhal processes in the respiratory or alimentary tracts.

From my experiments on animals I am satisfied, as are all experimenters, that tuberculosis is never produced without the presence and action of the tubercle bacillus, but my own observations on human patients, especially on children, confirm

those of many others, that unless the tissues are weakened or damaged—*i. e.*, the soil is prepared—there can be no reaction between the bacillus and the tissues which can end in the production of a tuberculous lesion. The exciting cause must be present, but in the human subject at any rate there must also be one or more predisposing causes. In the lung this predisposing cause appears to be catarrh; that is, a congestion of the vessels of the mucous membrane, accompanied by some slight proliferation of the epithelial cells lining the air vesicles, with an increased pouring out of fluid and an emigration of a larger number of white blood cells. In the air vesicles of the lung, especially when expansion and contraction are weak or imperfect—*i. e.*, at the pulmonary apices in adults, near the root of the lung in children (and in monkeys), beneath areas of adhesion between the pulmonary and costal pleuras, and at the base of the lung when there is adhesion of the pleuras in this position, especially if the liver be adherent to the under surface of the diaphragm—there is usually an accumulation of catarrhal products in which, if bacilli gain entrance and are allowed, undisturbed by any great amount of movement, to multiply, to produce their special products, and to cause those degenerative changes with which they are found to be associated causally. Once give them a footing under these conditions, and they are in a favorable position to produce tuberculosis.

It is evident from what has already been said that the tubercle bacillus may reach the lungs by way of the air passages; that they make their way to those points at which there is least movement and in which, as a rule, there is some degree of collapse, often associated with a condition of catarrh—*i. e.*, a condition in which the protecting layer of epithelium has been damaged, the lung tissue then being in the same position as the hand on which the epithelium has been damaged. From this coign of vantage they may be distributed, still by the air channels, to almost every part of the lung, setting up a condition of tuberculous catarrhal pneumonia characteristic of the later stages of the so-called acute phthisis. In many cases this acute phthisis is nothing but an acute secondary pneumonic tuberculosis following a rapid distribution of tubercle bacilli imbedded in the caseous material derived from a chronic primary focus. It should be noted that in these cases caseation of the epithelial tissues usually takes place at a comparatively early stage of the process.

So much for the distribution by the air passages. We now come to a second system of distributing or infection channels, which appears to play a prominent part in every case of tuberculosis, chronic or acute—the lymphatic system. Between the cells of the tissues, and especially around such structures as the blood vessels, even the smallest of them, there is a kind of network of channels or spaces (the lymph spaces) that has sometimes been compared to the system of pores seen in a sponge. Such terminal spaces gradually lead into small definite channels, and finally into tubes or vessels of considerable size and with distinct walls—the lymphatic vessels. These tubes lead to little filters known as lymphatic glands. Much of the fluid that in the process of nutrition passes from the blood vessels passes into these lymphatic spaces, and from this fluid the tissues take up their nutrient material, throwing back into it their waste or effete products. The fluid throws some of these waste materials back into the blood, but certain of the more solid particles pass to the lymphatic vessels, and by them are carried to the lymphatic glands, where the coarser particles are filtered out, and where, too, certain changes appear to be effected even in the composition of the fluid lymph.

Let me give you an illustration. If a patient tattooed on the forearm could be examined within a few days of the operation, small particles of pigment would be found in the tissues (cells in and lining the lymph spaces) at various points between the tattooed patch and the elbow, and even above the elbow. If the patient were to live for some months and then were to die, it would be found that, except at the tattooed patch and in some little hard nodules in front or at the side of the elbow or under the armpit, there is no pigment, but in these latter positions black, red, or blue pigment, according to the material used by the artist, has accumulated, often in considerable quantities, so that it can be seen with the naked eye.

Most of you know how the glands under the arm swell

after vaccination. This is because the lymphatics of the arm carry the vaccine virus to the glands, they are irritated by the vaccine matter, there is proliferation of cells, swelling of fibers, an accumulation of fluid, and enlargement of the whole gland.

Exactly the same arrangement of lymph spaces, lymph channels and lymphatic glands is met with in the lung. There are spaces around every vessel and bronchus and between the finer tissue elements; these open into lymph vessels which in turn convey the fluid to the lymphatic glands situated at the root of the lungs. It is important to bear this arrangement of the lymphatics in mind; for we find that in tuberculosis of the lung the tuberculous virus is carried from the air vesicles by the lymphatics to the lymphatic glands. The tubercle bacillus or its products appears to exert some irritant effect directly upon the cells lining the lymph spaces, as a result of which, just as in the air vesicles, we have a proliferation of the cells and a formation of new tissue sometimes resulting in caseation, or the formation of a soft pulaceous mass which is supposed to resemble cheese; at others—and this is a point to be especially borne in mind—in the formation of fibrous tissue.

As regards this formation of fibrous tissue, it may be well to point out that the most marked feature in chronic tuberculosis is the formation of fibrous tissue in the pleura immediately above it; and it is an easy matter in most cases to determine roughly the comparative duration of the disease at any part of the lung by noting the thickness of the pleura and of the interlobular septa; so that in a chronic phthisis in which the patient succumbs rapidly as the result of an acute consolidation, there is usually wellmarked thickening at the apex; this gradually shading off to the lower part of the upper lobe and being represented merely by a thin film of fibrin over the lower lobe.

Where the tuberculous process specially affects the adventitia or outer coat of the bloodvessels and bronchi, this fibrous tissue formation is often exceedingly well marked. In some cases it would appear almost as though the tuberculous tissue, at first of a type which may be compared to an irregular granulation tissue, may become converted into fibrous tissue directly; but it may be accepted as a general statement that where the tubercle bacillus manages to obtain a footing, it brings about a certain degree of caseation; but that in the immediate neighborhood of this caseous material which in some sense appears to act as a foreign body, the fibrous tissue is partly at any rate the result of the action of this foreign body upon endothelial cells or connective tissue cells, which after all, must be looked upon as cells of an endothelial type.

Wherever this fibrous tissue is formed, it affords evidence of a good reaction on the part of the tissues and therefore of the powers of resistance; it is by the formation of this fibrous tissue around the areas of caseation that they are cut off and the lesion localized. Where this localization is incomplete, as it often is, the bacilli pass along by them to the lymphatic glands, here giving rise to proliferation, caseous degeneration or fibrous tissue formation, just as is the case along the lines of the lymphatics. Having once reached the glands at the root of the lung, the process may, for a time, be localized; but unless the conditions are favorable and what we may call the reaction of the tissues is good, the tuberculous virus may be carried from point to point, successive glands in the neighborhood localizing the disease for a time, but ultimately allowing of the passage of the virus to other organs.

In connection with the invasion of lymphatic glands by the tubercle bacillus, it should be noted that once a lymphatic gland is affected, the course of the lymph circulation may be diverted; and again that any area usually drained into a lymphatic gland becomes much more readily affected when that gland becomes tuberculous than before this takes place; I think I have seen cases in which the lymphatic gland appears to have become caseous or cheesy before the area drained by it has become tuberculous. It is somewhat difficult to prove this, but I show you a specimen in which we have an exact localization of tuberculous area to that part apparently drained by a small gland at the root of the lung.

The third method of transportation of the tubercle bacillus from one point of the body to others is by way of the bloodvessels. For some time it was supposed that the acute miliary

tuberculosis that so frequently supervenes on the more chronic processes, was something essentially different from the larger primary lesions; but the identity of the two sets of lesions had been accepted even before Koch had pointed out that the exciting cause of the two processes was the same. It was difficult to determine, however, how the tubercle bacillus made its way from the primary lesion to every organ and tissue of the body. Weigert was able to point out that in a case where there was tuberculosis of the wall of the thoracic duct, the bacilli were carried from this lesion to the veins, from which they passed through the heart, and thence were distributed to the capillaries of every part of the body. In these capillaries, blocking them and becoming attached to the endothelial lining, they again set up a proliferation in and around the capillary vessel, as a result of which the minute tubercles met with in this condition soon became manifest to the naked eye. (Section shown.)

It must be remembered that these different methods of spread of the virus seldom occur alone. Whenever the air passages are affected we find, invariably, that the tubercle bacilli make their way into the surrounding lymph spaces, there giving rise to the proliferative and regenerative changes already described. Similarly, we find that in acute miliary tuberculosis there is, in each nodule, evidence of the invasion of the lymphatics by the tubercle bacillus, and it is because we have this affection of the lymphatics that the various lesions ultimately become localized. It is only through them that we can have a stimulation and proliferation of the connective tissue cells, new formation of fibrous tissue, and localization and absorption of the diseased tissues. I mention these methods of spread of the disease because in the various kinds of tuberculosis met with by the clinician, we have ample evidence that one or other predominates at different stages of the disease.

It may be well here to indicate, briefly, the history of a case of pulmonary tuberculosis, especially as by referring to this history in its various phases we may be able to gather how it is that at one stage the disease may be perfectly curable, but how it is that, as the disease advances, the chances of permanent or even partial cure are more or less rapidly diminished. I wish you to pay special attention to the periods at which the various processes come on; and also the times during which they are prolonged; otherwise it may be difficult to understand why a patient who has had phthisis for perhaps 2 years or 3 years and appears to have lost very little ground indeed, should suddenly begin to go down hill rapidly and die within a few months.

It has already been mentioned that in a case of phthisis apical catarrh is the first condition noticed, this being accompanied by congestion and followed by some consolidation, the result of proliferation of the epithelial cells, such cells gradually accumulating and coming to fill the air vesicle. This breeding-ground for the tubercle bacillus may gradually spread in area; but it will be found that the bacilli causing degeneration of the epithelium make their way into the surrounding lymph-spaces, there, especially if the tissues are well nourished, giving rise to the formation of fibrous tissue.

If at this stage the patient be placed under favorable conditions, of nutriment, of rest, so that the waste products of the body may be carried away regularly and systematically, the reaction of the tissues is so complete that the dead patch is practically surrounded and cut off; the bacilli remain inactive in the dead mass; or they may even be killed. The degenerated tissue is absorbed very gradually and there may be complete "cure," especially when the initial lesion has not reached any very great size. The loss of respiratory surface is so slight and the reserve so great that the patient may be considered to be practically normal again.

If, however, the patient be not placed under favorable conditions, or if after a short period of treatment he returns to his old life and habits, this focus of dead material may ultimately break through the surrounding layer of limiting tissue and a further considerable patch of tuberculous consolidation may be the result. (Slide.)

In most cases, especially if there be intermittent congestion of the surrounding tissues, the degenerated or caseous material may become softened, and it is during this stage of softening that secondary infection goes on perhaps most readily.

Let us suppose that this mass cut off from the bronchus with which the air vesicles were originally associated, extends to the wall, perhaps of another bronchus; as it advances in this wall it cuts off the vascular supply, first that of the peribronchial tissue, and then that of the submucous tissue, until at last by destroying the vitality of the bronchial wall, it brings about a process of ulceration; then the tuberculous material with its contained bacillus may immediately be carried into the air passages, whence it may be expectorated almost entirely, though in most cases a certain proportion of the softened material along with the bacilli is carried to other areas, where fresh tuberculous catarrhal pneumonia is induced, and the whole process may be repeated, but upon a more extensive scale. This process may be again repeated—at each repetition larger and larger areas being affected. It is evident that in such cases as those just described, the loss of lung tissue may be very great indeed, whether it be broken down or not—*i. e.*, whether the lung be merely consolidated or whether it be cavitated. Even the great reserve mentioned above is unequal to the draft made on it, and even should the patient be patched up for a time, he must face the fact that he is not cured, and never can be, though under proper treatment and with great care he may continue to lead a useful if not very active life.

It is sometimes difficult to understand why the small hemorrhages so characteristic of the early stage of phthisis should occur so frequently, especially when we remember that in the tuberculous areas themselves the bloodvessels are practically obliterated. It must be remembered, however, that around each tuberculous area the conditions of the vascular circulation are somewhat altered, owing to the fact that some of the vessels are closed; as a result of all this, a collateral circulation must be set up and maintained. Moreover, an increased quantity of blood is required to meet the wants of the proliferating tissues; but we find that the hemorrhages usually take place as the result of some extra temporary strain, and are an indication of local changes. It will be noted that in some of the specimens I show that we have a systematic invasion of the lung commencing at the apex and gradually working toward the base. It will be noted, moreover, that the basal processes are always more extensive, that the consolidation is more diffuse, and the degeneration more rapid than at the apex; that we have in fact a more markedly caseating catarrhal type in this position than at the apex. The whole of the lower lobe of the lung may be invaded in a few weeks, especially when the resisting powers of the tissues have been gradually broken down by overwork, general ill health, want of sufficient nutriment, imperfect oxidation of the blood and accumulation of waste products in the tissues.

These factors do not act at once; but at work over considerable periods they gradually wear down the resistance of the tissues, with the result that the tubercle bacillus finds an easy prey wherever it finds lodgement.

In addition to the catarrhal process, there is in most of these rapid cases of basal phthisis a more acute pneumonic condition, the air vesicles in the spaces between the catarrhal pneumonic patches in such cases being filled with a fibrinous exudate. This process seems to be associated with the alterations in the circulation, but partly to be the result of a secondary infection; wherever it occurs, however, it is a serious factor in the production of consolidation, and always accelerates the rapidity of the process, patients so affected, as a rule, dying quickly.

It will be seen at once from this rough description that a physician has a considerable period during which he may hope to treat his patient successfully, but that at any moment almost, a series of more acute changes may supervene, after which he has no right to expect recovery; though it must be acknowledged that in a few cases patients do recover even after such expectation is no longer justifiable. Nature is always more powerful than we give her credit for, and often helps us when we have given up all hope. This, however, is something we should never presume on, and the importance of the early diagnosis of tuberculosis can scarcely be too keenly appreciated, nor that of early treatment.

We now come to a phase of the question that has been recognized by many physicians, but one that is not so generally recognized by the patient. A patient who has once suffered

from tuberculosis must remember that although he may be partially protected (though of that, however, we as yet know nothing), he does not enjoy any definite immunity against future attacks of the disease; and it is absurd for any one to decry a system of treatment because it does not confer a lifelong immunity to the disease against which it is directed. I show you a specimen in which there is an old scar in the lung, from which all tuberculous material had disappeared leaving a little nodule of pigmented fibrous tissue surrounding a few particles of calcareous matter. That patient suffered from phthisis many years ago and had recovered, but you will see that throughout the remainder of the lung we have now the lesions of an acute miliary tuberculosis; the patient succumbed to an infection in all probability of entirely new origin, though it is possible that it may have been the outcome of some old but latent lesion, either in the lung or in some other part of the body, from which tuberculous virus has made its way into the bloodvessels, and thence has been distributed throughout the body.

Such a case as this, to my mind, though exceedingly encouraging in many ways, should lead us to insist that patients even after discharge from sanatoriums where the treatment has been successful, should continue the treatment, perhaps in a modified form, throughout their whole life; as it is impossible to state when a patient can come back to the old conditions of life with impunity; in fact, one may lay it down as a general proposition that it is only as we insist on the improvement of the conditions of life wherever such improvement is possible, that we shall be able to diminish the morbidity as apart from the mortality of tuberculosis. It is here that the medical officers of health, and sanitary officers can play so large a part; and that an institution of this kind can do so much to spread a knowledge of the importance of light and air in the home and in the workshop, of sufficient food even though plain, of the danger of prolonged periods of overwork, except in the case of the very strongest; and of the importance of periods of rest during which the organs and tissues of the body may not only be built up, but may get rid of the waste material that accumulates so rapidly during periods of active exertion.

This brings us to a very important question indeed. Although I have every faith in sending patients who can afford it, to places where they can comfortably remain in the open air and where there is plenty of light, I think there is a danger, and a very great danger, of overlooking the fact that the open-air treatment may be carried out at the patient's home, and that so far as this branch of the treatment is concerned, it is not so much a matter of getting a good climate as of getting pure, fresh air for the patient.

There can be no doubt that the sanatorium treatment has been successful, not because of any special climatic conditions associated with each institution, but because whatever the climate the patient has been encouraged to live practically in the open; diet, exercise, and rest, of course, being carefully attended to. All acknowledge that a sanatorium treatment is of inestimable value in tiding over the difficult and dangerous early period of the disease; but it will be still more valuable just in so far as it teaches the patient to carry out in his own home the principles and methods adopted in the sanatorium. It always seems to me that a patient will be much more likely to have faith in the efficacy of the methods used, if they are carried on in familiar surroundings and under conditions of climate, etc., to which he is usually exposed. If he is sent to a special climate resort, he is apt to think that the success of his treatment depends on something special in the climate, and while this is of course the case to some extent, in so far that in a bright, dry, bracing climate the open-air treatment is more agreeable and a cure effected somewhat more quickly perhaps, there are no fundamental differences between the two, the closer you can bring your patient to his every-day manner of life during treatment the more likely he will be to carry out your instructions after discharge from the sanatorium.

I may say that at Cambridge, a place little above the sea-level, situated in the fen district, where fogs are frequent and sometimes very dense, great success has been attained in the open-air treatment of phthisical patients in the Addenbrookes Hospital. I mention this fact for what it is worth; but I think

that it bears out the contention of those that the method of treatment is in most cases more important than the exact place in which it is carried on.

(Lantern slides were shown to illustrate a number of the points mentioned. Most of the sections were made through the whole lung, and were thin enough for examination under a quarter-inch objective.)

Ladies and gentlemen, those who are responsible for the inception, organization, and working of this institution, have undertaken what most of us consider to be one of the most beneficent works on which men can engage. The endowment is munificent; and as the workers are both capable and enthusiastic, I think that we may look forward with very bright hope to the outcome of the work carried on. But the work to be done cannot all be undertaken even under the favorable conditions that here obtain; and I would ask you not to be disappointed should you not attain all that you hope in the immediate future. There is much quiet and steady spade work to be done. You will, I know, relieve and cure many patients; but you have then touched but the fringe of a great problem. You have to determine the exact pathologic conditions met with in individual patients and in groups; you have still much to learn concerning the condition of nutrition, of waste, and of repair; you have physical problems, chemic problems, bacteriologic problems, and others of the greatest complexity; these can be undertaken only by men skilled in methods and trained in accurate observation. They may have to work for years before they are able to gain results that can be utilized, or that can be brought into a great scheme of knowledge, from which further advances can be made; but we may all entertain the hope, and one well founded, that under honest, persevering, patient investigation even the most difficult problems may be compelled to give up their solution. While working for the benefit of the individual, we must keep our mental vision fixed on a point beyond: on the possibility of preventing the invasion of the tissues by the tubercle bacillus; of studying the life-history of this organism, so that in time, as we gain the knowledge of the conditions under which it exists, both outside and in the body, we may gradually so circumscribe its sphere of operations that it may no longer remain a factor of disease, especially when we are wise enough to insist on those improved sanitary and social conditions without whose aid the tubercle bacillus even today would lose much of the terror attached to its name. I congratulate the Henry Phipps Institute on what it has already achieved; but I hope for it and those associated with it a still more useful, beneficent, and brilliant future.

Condition of Lepers in the Philippines.—After having spent the last 11 years caring for the children of the lepers of the Hawaiian Islands, Sister Albana, of the Franciscan Order, who was formerly Miss Miriam Sluder, of St. Louis, has arrived in that city on a visit to her parents. She said that the common belief that children of lepers inherit the disease is erroneous. "We take the children when they are 2 days old, and we have never had a case where leprosy has developed in after years. The children mostly all come from the Island of Molokai, where the leper colony is located."

Too Much Loss of Life by Railway Collisions.—The *Public Ledger*, Philadelphia, says, editorially: "The Interstate Commerce Commission declares, in its annual report just made public, that the most prominent feature in the year's record of train accidents is the loss of life in collisions. The record is not materially worse than that of last year, but the Commission says that the exhibit shows continuing conditions which demand serious consideration. It is noted that fatalities from collisions are due to causes which have never been adequately and comprehensively considered by any department of the Federal or State Governments, and but slightly by State Railroad Commissions. The Interstate Commerce Commission offers no remedial suggestion. The number of passengers killed in this class of accidents is not large relatively to the number of passengers safely carried, but the Commission well says that the killing of any large number of passengers in the course of a year in a single class of accidents deserves attention. If the number of persons thus sacrificed were diminishing from year to year, the situation would be more hopeful. It is gathered from the tenor of the Commission's report that collisions would not be so frequent if Legislatures or railway Commissions would investigate the causes more thoroughly than any of them have yet done. If such 'accidents' are avoidable, it is time that preventive legislation were enacted."

1. The Causes of the Occasional Failure of Operation to Cure Gallstone Disease. WILLIAM J. MAYO.
2. Intestinal Antiseptics; Their Uses and Limitations. J. A. STORCK.
3. Notes on Pulp Technic. MARTHA ANDERSON.
4. A Simple Method of Treatment of Hemangioma. CARL BECK.

1.—Failure to Cure Gallstone Disease.—W. J. Mayo reports that in 631 operations but 3% required a secondary operation. These were complicated cases due to delay in seeking surgical relief. Some patients have colic following a cholecystostomy, sometimes accompanied by transient jaundice, due probably to a crippled gallbladder becoming filled, and on account of recent adhesions, not emptying properly. A second operation may not be necessary unless there are other evidences of trouble. The most common cause of future symptoms is incomplete removal of stones. By using the finger even a small calculus will rarely be overlooked. Before the development of Robson's technic it was not easy to locate a stone in the cystic duct. When impacted, cholecystectomy is generally indicated. When cholecystostomy fails it is often due to obstruction in the duct from stricture caused by the irritation of a stone. In septic cases severe symptoms, especially in colon infections, may result from too early closure of the fistula. A calculus in the common duct may be overlooked if the cystic duct also is obstructed. The ducts should be explored with the finger in every case before opening the gallbladder. The condition of the pancreas should be ascertained at the same time, and if pancreatitis is present drainage should be kept up a long time, or a cholecystenterostomy with a Murphy button should be performed. Cancer may be mistaken for inflammatory disease. A thick-walled gallbladder is suspicious, and as it is useless, should be removed. In cholecystostomy the bladder should be attached as high up in the incision as possible to prevent the bile gravitating away from the duct. Persistent biliary fistula usually means obstruction of the common duct. Postoperative adhesions are not always avoidable. Secondary separation may be necessary with the use of Cargile's membrane. [H.M.]

2.—See *American Medicine*, Vol. V, No. 20, p. 781.

3.—Pulp Technic.—M. Anderson in preparing pulps for demonstration of nerve tissue has hardened them in formalin, Müller's and Ehrlich's fluids, and in Urigert's chrome alum solution. Sections cut after freezing were then stained by one of the following methods: Urigert's method for medullated nerves, osmic acid and hematoxylin, Mummery's iron and tannin, iron and hematoxylin, Freund's gold, Underwood's gold, lemon juice and gold. With iron and hematoxylin the fibers in some places could be traced to the apex of the pulp. [H.M.]

4.—A Simple Method of Treatment of Hemangioma.—Carl Beck reports a case pronounced by some surgeons inoperable which was cured and with good cosmetic results by gradually transforming the masses of vessels into connective tissue by means of a subcutaneous suture. He passes catgut in a zigzag manner, first below the skin, then underneath the base of the tumor, then again under the skin, and so on, until the tumor mass is included in this continuous suture, which is then drawn tight and closed at the point of entrance of the needle. The circulation is thus shut off, though some blood can still reach the tumor, preventing gangrene. After a week the tumor seems smaller, the normal epidermis, tense at first, becomes soft and elastic, and grows. This procedure is repeated until the tumor has been diminished to the smallest possible nodules of connective tissue. These are excised, and the borders approximated in fine linear union. The islands of normal skin enlarge within a few weeks to 2 or 3 times their size. In the arterial and mixed varieties of hemangioma it is necessary to ligate the largest afferent vessels also. [H.M.]

1. Diffuse (Combined) Degeneration of the Spinal Cord. E. W. TAYLOR and G. A. WATERMAN. (From the Department of Neurology, Long Island Hospital, Boston Harbor).

2. Historical Notes on the Laws Governing Civil Malpractice in the Ancient Times and Middle Ages. CHARLES GREENE CUMSTON.
3. The Bitzer Homicides. GEORGE P. TWITCHELL.
4. Malaria and Mosquitos of Worcester: A Year's Observations on the Habits of *Culex* and *Anopheles*. WM. W. MCKIBBEN. (Continued.)

1.—Diffuse (Combined) Degeneration of the Spinal Cord.—E. W. Taylor and G. A. Waterman report 2 cases of this lesion—1 patient having shown no anemia or other cachexia; the second being a person suffering from pernicious anemia. In the first there was marked arteriosclerosis of the circle of Willis and the arteries of the internal portions of the brain—internal capsule. In the second, the cord lesions were sharply limited to the dorsal and lateral columns, but not anatomically confined to neuron systems. The lesions of the first case, though in general similar, were much more diffuse in character than those in the second, and more widespread, though less compact. This fact is worth noting, as a number of prominent writers have maintained that the converse is apt to be the case. The writers, after brief review of recent papers, see no reason for changing their previous statement that no fundamental characteristics of the lesion have been found depending on different causes. For the present "diffuse combined degeneration" is a sufficiently exact designation of the usual anatomic alterations. [A.G.E.]

2.—Laws Governing Civil Malpractice.—C. G. Cumston shows that medical liability has been sustained by all the courts of former times, and cites cases and refers to laws of the Egyptians, Greeks, Romans, and ancient German and French peoples to illustrate this fact. [H.M.]

3.—The Bitzer Homicides.—G. P. Twitchell gives the history of the case in which the accused claimed that the first shooting was accidental. The hair was singed. Experts for the prosecution experimented on cadavers with the revolver used, and at 6 inches the hair was not singed. Between 3 and 4 inches, the results were the same as on the head of the victim. Experts for the defense who used wigs in their experiments found they could singe the hair at a greater distance. [H.M.]

4.—The Habits of *Culex* and *Anopheles*.—W. W. McKibben describes the development of malaria in Worcester, infection being carried there by returning soldiers and cheap Italian labor. The increase in cases in the last 5 years has become serious. By locating the cases on the city map it was seen that Worcester was completely surrounded by a malarial band, the center of the city being practically free. The number of cases was found to be in proportion to the number of inhabitants and the proximity of anopheles. The condition most favorable to anopheles flying a great distance is a gentle breeze. *Culex* is much more local in its habits. The female anopheles attacks the hand viciously, striking hard without hesitation or song. It does not secrete so much poison as the *culex*, producing no wheal. Males of neither species could be made to bite. These live only a day or two after copulation. The females live a couple of months, some possibly surviving till the next season. The *culex* has a shrill song, the anopheles a low-voiced hum. The two species do not get along well together; the *culex* is so prolific it soon kills out the anopheles. The larvae and pupas develop into the adult form very rapidly under certain conditions. It is rare that anopheles larvae are found in accidental receptacles, such as tin cans. The writer describes minutely the biting apparatus and the effect of petroleum on the breathing tubes of the larvae, and ends by discussing methods of prophylaxis. [H.M.]

Medical Record.

December 26, 1903. [Vol. 64, No. 26.]

1. Tumors of the Pontomedullo cerebellar Space. Acoustic Neuromas. (Central Neurofibromatosis). JOSEPH FRAENKEL and J. RAMSAY HUNT.
2. The Present Status of the Treatment of Lateral Curvature. JACOB TESCHNER.
3. Intestinal Fermentation, as it Interests the Surgeon. ROBERT T. MORRIS.
4. The Submucous Resection of the Nasal Septum. FELIX COHN.

1.—Acoustic Neuromas.—J. Fraenkel and J. R. Hunt consider under this title, or that of "Tumors of the pontomedullo cerebellar space," a group of cases characterized by the formation of tumors (single or multiple) on one or more

cranial nerves. The acoustic nerve is most frequently affected, the second in order being the trigeminus. The writers give notes of 5 cases, 3 being tumors of the acoustic nerve, one a bilateral tumor of the acoustic, one a tumor of the trigeminus. Four were personal cases. The underlying causative factor is a teratologic one. The tumors are histologically neurofibromas. Very commonly they undergo sarcomatous change. They are often classified under the various headings of intracranial tumors. The clinical picture of these growths is that of tumors of the posterior fossa of the skull. They are distinguished from growths originating within the brain by the early appearance of symptoms referable to a single cranial nerve. The certainty of localization, the essentially benign nature of the growths, and their loose attachment to the meninges and nerve trunks make this group of tumors a favorable one for surgical interference. [A.G.E.]

2.—The Treatment of Lateral Curvature.—J. Teschner adduces evidence corroborating his views advanced some years ago, regarding the efficacy of gymnastics in the treatment of lateral curvature of the spine. He criticises rather severely other writers for their statements, and for advocating other methods of treatment, even though his be mentioned. Several figures accompanying the paper illustrate the good results of muscular efforts in the correction of marked deformity of the spine. The point most strongly emphasized is the necessity of the personal supervision of a physician who understands the method. Sending patients to ordinary gymnasiums is almost always of no practical benefit. [A.G.E.]

3.—Intestinal Fermentation as it Interests the Surgeon.—R. T. Morris writes briefly of cases in which there is an evident surgical factor in the production of an undue amount of intestinal fermentation. In them the surgical cause is so often overlooked and the case treated by medical means, that the writer believes it is well to classify some of them. The symptoms must not alone be noted, but they should be arranged in such order that they point toward the primary and fundamental cause of the disturbance. Among the peripheral irritators are peritoneal adhesions, those about the appendix and cecum causing more disturbance than those in the pelvis. The former, though, are less disturbing than adhesions about the gallbladder. This region has been a comparatively little discussed one, the recent article by Musser being of the greatest importance in this connection. An appendix undergoing normal involution is a frequent cause of intestinal disturbance. Cases due to loose kidney or general enteroptosis are more easily recognized. A large group of cases is dependent on eyestrain. Many cases marked by "chronic constipation since childhood," depend upon the presence of hypertrophic rectal valves. Many obscure cases clear up when the ganglia of the bowel wall are freed from irritation due to surgical disorders. [A.G.E.]

4.—Submucous Resection of the Nasal Septum.—Felix Cohn speaks of Krieg's method of performing the above operation and briefly describes the technic he has personally evolved since first employing the operation in 1888. For most cases local anesthesia with weak cocaine and adrenalin solutions is employed. The patient is placed on a table with his head slightly raised and turned away from the deviated side. Those laryngologists, who believe that perforations are a detriment and a subsequent annoyance to the patient had best not perform the operation, as perforation is a frequent accompaniment. Cohn is absolutely convinced that perforation is harmless. The results of submucous resection are uniformly excellent, after-treatment is entirely unnecessary, and the cure is permanent. Cohn recommends the operation because it has not been so widely adopted as it deserves. [A.G.E.]

1. On the Etiology of Pulmonary Tuberculosis in its Relation to Diseases of the Nose and Throat. W. FREUDENTHAL.
2. Remarks on Mechanotherapy. Massage, Bone-Setting, and Osteopathy. JOHN MADISON TAYLOR.
3. On the Natural Habitat of the Tubercle Bacillus. J. W. KIME.
4. A Method of Rapid Extirpation of Nasopharyngeal Fibromas, with Report of Cases. GORDON KING.

5. Things Every Tuberculous Patient Should Know. MARTIN L. STEVENS.
 6. The Genesis and Nature of Medicinal Dioxids. FRIEDERICH ELIAS.

1.—The etiology of pulmonary tuberculosis in its relation to diseases of the nose and throat is discussed by W. Freudenthal. He takes up first the nasopharynx and points out its predisposing conditions of an anatomic or physiologic nature that influence favorably the settling and development of bacteria. The wider the nasal passages and the drier the nasal mucosa, the more bacteria will settle in the nasopharynx, and vice versa. He believes that a rhinitis sicca, and even more an atrophic rhinitis, unfits the nose entirely for respiration. As a rule the bacilli penetrate the deeper tissues and enter the lymph current. Swelling and suppuration of the glands of the neck are not unusual, and are evidences of the path taken by the tubercle bacilli. Tables are appended showing the results of examination of the nose and teeth of a large number of individuals. In some cases the diagnosis of the pulmonary condition is also recorded. The author says that to him it is a matter of conviction that the dry and atrophic condition of the nose and throat produced by our unhygienic system of heating is one important factor in laying the foundation for tuberculosis and that if we wish to treat the tuberculous rationally, we must begin with the upper air tract. If we eliminate this factor we shall find it easier in many cases to reach the deeper seated lesions. [C.A.O.]

2.—Mechanotherapy, Massage, Bone-setting, and Osteopathy.—J. M. Taylor calls attention to the fact that masseurs, bone-setters, and osteopaths with good mechanical abilities and shrewd observation, have often gained renown for their power to set bones, readjust structures, and restore elasticity to shrunken or stiffened tissues, thus relieving disabilities large or small, or pain, or both. He calls attention to the fact that by massage or bodily manipulations much good can be accomplished. It is not to be expected that the physician could devote the time required by some of the more laborious and continuous or routine procedures. He might not be endowed with the strength or dexterity for these, but for the more scientific part he should at least direct and supervise knowingly. He could and should make use of the more delicate manipulations which are of far greater value. He says it is a most promising field for research for the experimental physiologist, and especially for the neurologist. The sphere of manual therapy lies in the ability of medical practitioners to influence centers of organic activity by mechanical stimulation through the vasomotor nerves, whereby less or more blood can be sent to parts according to their need. [C.A.O.]

3.—Habitat of Tubercle Bacillus.—J. W. Kime believes that all tuberculosis, whether of man or beast, were originally of bovine origin, and that in the cow is found the natural habitat of the disease. He believes that the cow furnishes the type of soil and tissue best adapted to the production of virile tubercle bacilli; also that the more immediate the transference of tuberculosis from the cow to man, the more deadly it becomes and the more readily it may be transferred back to the cow again; while cultures many generations removed from the cow lose much in virulency, are comparatively innocent in their effects, and are with great difficulty carried back to the source from which they took their origin. [C.A.O.]

4.—Nasopharyngeal Fibromas.—The method of rapid extirpation of these tumors is as follows: Under chloroform anesthesia a high tracheotomy is performed and a tube inserted. With the patient in the Rose position, the head supported by an assistant, and a mouth-gag in place, the index and little finger of the left hand are introduced in the nasopharynx to ascertain carefully the outlines of the tumor and the position and extent of its base of implantation. This step in the operation is of great importance, for as soon as the size and point of origin of the pedicle are made out, the fingers are to serve as a guide for the operation of a pair of scissors introduced through the nose on the side where the pedicle is more accessible. The scissors to be used for this purpose are a strong pair with long handles and short blunt blades, slightly curved on the flat. The closed blades are introduced carefully along the septum until the point can be felt in the nasopharynx. The instrument is then guided by the fingers to the pedicle

and with the convexity of the blade uppermost the pedicle is divided. The tumor can then be removed through the mouth and the hemorrhage checked. In this manner the bulk of the growth at least can be removed, and if the hemorrhage has been copious, the patient should be allowed a few days to recuperate before being subjected to further operation for the complete removal of what may remain behind. The cases reported demonstrate the practicability of the method of extirpation by the bucconasal route alone, whether aided or not by the precautionary measures of tracheotomy and carotid ligation. [C.A.O.]

5.—Maxims for the Tuberculous.—The article by M. L. Stevens is made up of maxims which every tuberculous patient should know—principles that should be repeated until they are so fixed in his mind that he cannot forget them. He takes up first the subject of cough and expectoration, then exercise and rest, open air, diet, medicines, clothing, bathing, alcohol, tobacco, etc., and finally maintains that the patient's cooperation with his physician must be full, honest, and complete. [C.A.O.]

Medical News.

1. Predispositions to Tuberculosis. JOHN B. HUBER.
2. The Indications for the Ligation of the Internal Jugular Vein in Lateral Sinus Thrombosis. SEYMOUR OPPENHEIMER.
3. Chorda Venerea. G. S. PETERKIN.
4. On the Reflex Eruptions of the Skin from Morbid Alterations in the Male Urethra. A. RAYOGLI.
5. The Treatment of Some Diseases of the Eye by Warm Medicated Sprays. DAVID T. MARSHALL.

1.—Predispositions to Tuberculosis.—J. B. Huber discusses hereditary, congenital, and postnatal predispositions. Hereditary tendency manifests itself in the scrofulous temperament, thoracic malformations, with defective development of the respiratory and circulatory systems, infantilism, etc. Functional modifications may be unaccompanied by anatomic stigmas, and give no hint of their existence until trauma or intoxication brings them to light. Tuberculous parents often impart a pernicious nutritive habit, making a fruitful soil for microbic growth. Congenital infection by Koch's bacillus undoubtedly exists. Bodily or psychic disorders in the parents, fatigue, convalescence after a serious disease, advanced age at the time of conception, causes accidental, or perhaps so slight as to escape notice, or such as may be transitional in the parents, may induce a vicious nutrition, making the organism receptive to infection. Tuberculosis at the beginning is purely local. The bacilli are not inhaled. The lung tissues are invaded through the alimentary canal and the bronchial glands. The frequency of the disease in the apex is due to immobility of the first rib in many persons, narrowed bronchial tubes, and pressure on the bronchi by inflamed glands. The anemia caused by exposure to cold means diminished resistance to the bacilli of the venous blood brought to the lungs from the thoracic duct before the blood is sent into the general circulation. Faulty metabolism plays an enormous part in predisposition. Alcohol stands in a causative relation, and also its accompaniments, unsanitary habits, poverty, bad food, and overwork. Insanity holds a subtle relation to it. Farmers are predisposed through their execrable diet, intermarriage, morphinism, constipation habit induced by cold outhouses, etc. Other diseases and certain trades predispose, also acute shock from trauma and chronic shock from nerve exhaustion. [H.M.]

2.—Ligation of the Internal Jugular Vein in Lateral Sinus Thrombosis.—S. Oppenheimer says that when there are the least evidences of septic changes in the walls of the vessel or the contained thrombus, with extension to the jugular, that vein should be ligated and the affected portion excised. The most difficult question to decide is that of preliminary ligation before exposing the sinus. The indications for the latter operation are septicemia or neuroretinitis. After exposure of the sinus, ligation of the jugular before further procedure with the sinus itself is dependent on one of two indications: 1. Disintegration of the lower portion of the clot as shown by aspiration. 2. The transmission of respiratory movements to the sinus. After the sinus has been opened, two conditions call for ligation of the vein: 1. Extension into it of a thrombus becoming

purulent. 2. A large firm thrombus filling the sinus and extending well into the vein. Personal experience of the writer indicates that the vein should be ligated whenever local symptoms indicating its involvement are present. [A.G.E.]

3.—**Chorda Venerea.**—G. S. Peterkin discusses the etiology, symptomatology, preventive and active treatment of this condition. In addition to the general management of the condition, he emphasizes a hygienic detail, the value of which is as yet only partly recognized by the profession. That detail is the massage of the prostate and seminal vesicles during acute gonorrhea. This is efficient in preventing erections, congestion of the parts is lessened, and a beneficial psychologic effect upon the patient is produced. It obviates the necessity of disordering the systemic condition with bromids, camphor, codein, etc. Involvement of the prostate will thus be early detected. The technic of the procedure is given, the main points being thorough irrigation of the anterior urethra, followed by filling the bladder with solution, this being retained during massage and aiding manipulation, as well as preventing involvement of the posterior urethra. [A.G.E.]

4.—**Reflex Eruptions of the Skin from Urethral Disease.**—A. Ravogli says that these eruptions may be reduced to two, herpes and pruritus. An important question is whether the excoriations resulting from herpes may favor venereal infection. In all cases of herpes progenitalis Ravogli has found a chronic posterior urethritis. The presence of mucus in this condition is believed to cause irritation of the filaments of the internal pudendi and thus produce herpes. In the same way the cause of pruritus must be looked for in the condition of the urethra. Treatment must be applied to the urethra and perhaps the prostate as well as locally to the eruption. Ichthyol has given the best results in the latter condition. [A.G.E.]

5.—**Treatment of the Eye by Warm Sprays.**—D. T. Marshall uses a steam atomizer, with the patient seated close in front, looking directly into the tube while the lower lid is pulled down. After spraying, applications may be made. Cases of marginal blepharitis heal with surprising rapidity after spraying, followed by yellow oxid or other ointment. It is difficult to get such patients to remove the crusts from their lids. It is indicated in all diseases of the conjunctiva, in corneal ulcer infiltration and interstitial keratitis, and in iritis. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Erythromelalgia and Raynaud's Disease.—As all our readers know, the declining years of the past century added to our previous overstock of interesting, although approximately unmanageable diseases, two curiously contrasted ones of comparatively rare occurrence. We allude to *erythromelalgia* and *Raynaud's disease*. The former, which is by far the more uncommon, owes its birth and baptism into clinical and scientific history to Dr. Weir Mitchell, who in his original description informs his readers that: "Erythromelalgia is a chronic disease, in which a part or parts of the body, usually one or more extremities, suffer with pain, flushing, and local fever, made far worse if the parts hang down." The less rare condition of Raynaud's disease is one in which the extremities present *asymmetric* display of evidences of profound vascular and nutritional derangement, in which pallor, congestion with lividity, and local gangrene are the characteristic features—in effect, "a local syncope, a local asphyxia, or a local death." Dr. Skirving, of New South Wales, recently exhibited to his medical society a case of this latter condition, in a miner, aged 36. The patient was of distinctly neurotic temperament, and had lived a life of physical hardship and exposure; but had no specific history, and presented no discoverable organic lesion. He attributed his condition to the fact that he had "worked in wet claims." Eighteen months before, he began to notice that at times both his feet "went dead." They

became pale, sodden-looking, and cold to the touch. At the same time, tactile, painful, and thermal sensations were equally blunted. There was never any dissociation of sensibility, such as is met with in some cases of other neurotrophic lesions, of which syringomyelia is a notable example. There had never been much pain, seldom any cyanotic lividity, and never any approach to actual gangrene. A patient suffering from erythromelalgia was simultaneously exhibited for the purpose of demonstrating and emphasizing the contrast. The patient, also a male, was 40 years old. He was also of neurotic temperament; was perfectly temperate in his habits, and had no specific history. His physical trouble commenced about 6 months before—after a long period of worry and physical overexertion. He first noticed pain and throbbing in the left fingers; then uncomfortable sensations developed themselves by degrees in the hands of both sides. Tactile sensibility appeared somewhat heightened; the other sensations had continued normal. The fingers had grown red and hot; at the time of exhibition they were "somewhat swollen," and they "show at times a tense, rosy glossiness." All the conditions and feelings are intensified when the hand hangs down. Stress was laid on the fact that no stage of pallor had preceded the development of the heated and flushed condition of the left digits. There was some loss of muscular power, and there was diminished response to both forms of the electric current, and more especially to the faradic. When the affected fingers develop their full tint of rosy redness, they proceed to sweat profusely. The symptoms are least troublesome in the morning, and increase markedly toward night. Those two cases of rare and but recently recognized disease are indeed curiously contrasted. The symmetry of the one and the asymmetry of the other are almost as definitely opposed as the vasoconstriction of the former and the vasodilatation of the latter. With regard to the primal etiology of the respective conditions, it is probable that in the case of Raynaud's disease, the view first propounded by the discoverer still holds its own, viz., that the vasomotor centers are unduly irritable, and that the causal stimulus is usually peripheral—such as the application of cold, and the efferent impulses reflected back from the neural centers lead to paroxysmal contraction of the arterioles. In the case of erythromelalgia, the nearest approach to a satisfactory explanation of the conditions which present themselves—although by no means a satisfactory one—is offered by the suggestion of the existence of a peripheral neuritis which affects the vasomotor fibers only.

REVIEW OF LITERATURE

Lathyrism.—This is a disease that has been noted, especially in India, as being due to poisoning with various kinds of the family *Papilionaceæ lathyrus*, or common pulse. A. G. Hendley¹ has had the opportunity of studying this disease. It comes on suddenly with stiffness, weakness, and heaviness in the legs, constituting a sort of spastic paralysis. The weakness rapidly progresses, until progression becomes difficult or impossible. No other parts of the body are affected, and the patient feels perfectly well otherwise. The gait is of a peculiar, spastic character, termed by the author a "paralytic goose-step." There is no wasting, loss of muscular tone, or loss of sensation. The tendon reflexes are much exaggerated. Investigation has shown that only certain kinds of lathyrus are poisonous, and that the poison is probably contained in the skin or husk of the seed. Exposure to severe wet and cold seems to be required to precipitate an attack. No typical pathologic condition is found after death. The disease does not seem to cause death directly, but the paralysis is incurable. [B.K.]

Distribution of the Nitrogen in Urine in Pathologic Conditions.—M. Halpern² finds a diminution in the percentage of

¹ British Med. Jour., September 28, 1903, p. 707.

² Zeit. für klin. Med., Bd. I, p. 355.

urea nitrogen in cases of nephritis, carcinoma and inanition. This diminution, however, is not constant. Replacing this diminished quantity of urea there is an increase of the ammonia and extractives. There is no relation between the nitrogen of the urea and that of the so-called amido acids. The distribution of nitrogenous bodies in the urine was normal in cases of lymphatic anemia, severe essential anemia, splenic anemia, pulmonary tuberculosis, and gallstone disease. [B.K.]

The Shiga Bacillus and Dysentery.—The etiology of dysentery is still an unsettled question. There are undoubtedly 2 varieties of the disease—one caused by amebas and another due to bacterial agents. Since Shiga has demonstrated his bacillus in the dysenteric epidemics of Japan, others have succeeded in finding the same organism in European countries. Moreover, Shiga has been anticipated by Chantemesse and Widal, who 10 years before him discovered the same bacillus. G. N. Kasarinoff¹ has made a series of experiments on guinea-pigs and rabbits. He succeeded in producing artificial dysentery in these animals, and concludes that the bacillus described by Shiga in 1898 (though known for several years before this date) is the etiologic factor in the dysentery of moderate climates, while the same disease occurring in the tropics is due to amebas. [L.J.]

Bacteriologic Examination of the Blood in Scarlet Fever.—The investigations of G. Jochmann,² show that in 15.5% of his cases streptococci were found in the blood during life. They were never found at the height of the exanthem or in the first 2 days. The symptoms were no different in those showing streptococci than in those not showing them. The organisms were never found during life in foudroyant cases, but those in which they were found almost always ended fatally. The number of streptococci found in the blood during life is small compared to that found after death. Excluding those that died from scarlatinal nephritis, about one-half of the fatal cases showed organisms in the blood shortly before death. Of 70 cases examined postmortem, the results were negative in 16. As the organisms are much more likely to flourish in the dead body than in the living, these results show that the presence of streptococci in the blood is not a necessary factor in the picture of scarlatina. Cases were found in which all internal organs were sterile, but in which streptococci were found in and around the tonsils; and in a few cases the organisms could not even be demonstrated in these portals of infection. Hence, the author concludes that streptococci may play an important part in the disease, but that they cannot be positively assumed to be the cause of the disease. [B.K.]

The Frequency of Joint Affections in Hereditary Syphilis.—E. Hippel³ has found joint affections in hereditary syphilis frequent, especially in cases which during their first years were insufficiently treated with antiluetic remedies. Individuals with parenchymatous keratitis usually belong to this class. Of 77 such patients, 56% presented joint lesions; in most of them the ocular and joint diseases existed either simultaneously, or the arthritis preceded the ocular disease. The knee-joint was oftenest the seat of the disease, and in nearly all cases both joints were the seat of a serous effusion of long standing. As the lesion usually occurs between the fifth and twentieth year, and is often unassociated with other signs of syphilis, the diagnosis may be almost impossible. Subjective symptoms are very rare. A positive diagnosis can always be made with antiluetic treatment, which produces a cure in most every instance. [E.L.]

Influence of Infectious Diseases on Leukemia.—W. Neutra⁴ reports 2 cases of lymphatic leukemia, in both of which a streptococcal infection caused a fall of the leukocytes to normal or even below. The author collects 19 other cases from the literature. Malignant neoplasms are regarded by some as being of infectious nature, and the author has found a case in which a tumor had a similar influence on the course of leukemia. The intercurrent infection is almost always one which would produce leukocytosis in an otherwise healthy person. No other disease has been known to influence the

leukemic process. Various substances have been known to influence the leukocytosis of leukemia, such as quinin, cinchonic acid, tuberculin, etc. The probabilities are, however, that the fundamental cause of leukemia has not been affected, the diminution in leukocytes being merely symptomatic. The theories as to the nature of this influence are various. The author believes the most probable to be one of leukolysis. This is supported by the demonstration of increased uric acid excretion at the time of the diminution in leukocytes, and also by the occurrence of finely granular masses in the blood. [B.K.]

Tardy Hereditary Syphilis.—Jordan¹ publishes the details of 2 cases of hereditary syphilis: 1. An officer with an effusion into both knee-joints, which had been treated unsuccessfully for a long while; it yielded to mixed treatment. Other reasons for considering the condition syphilitic were the simultaneous appearance of the affection in both joints, the absence of pain, the slight disturbance of function and the failure of all usual methods. 2. A boy of 5 with effusion into both knee-joints and parenchymatous keratitis; no other symptoms existed, nor could a history of syphilis be obtained. Mercurial inunctions produced a cure. Jordan advises in all cases of bilateral knee affections which have not yielded to ordinary treatment, the institution of antiluetic procedures which must be carried through energetically. [E.L.]

Blood and Urine in Bilharzia Disease.—S. R. Douglas and F. W. Hardy² give a brief review of the symptoms and other characteristics of Bilharzia disease. In the blood they find a considerable increase in the percentage of eosinophiles, and a proportional diminution in the number of polymorphonuclear leukocytes. A large proportion of eosinophiles was also found in the urinary sediment. [B.K.]

Spinal Puncture in Uremia.—D. C. McVail³ reports in abstract 2 cases of uremic convulsions with coma, in which the symptoms were relieved by spinal puncture, the cerebrospinal fluid being allowed to drain away. The author believes that these cases prove that the convulsions and coma are due to sudden increase of intracranial pressure, and not to uremic poisoning of the nerve centers. He therefore recommends spinal puncture as a therapeutic measure in such cases. [B.K.]

Primary Tuberculosis of the Tonsil.—Emil Glas⁴ reported 2 cases of primary tuberculosis of the tonsils. In one case there was a milary tuberculosis of the tonsils which produced, by continuity as well as through the lymph and blood channels, an infection of the other organs. In all 3 cases the tonsils were hypertrophied. In 1 case milary foci appeared in the tonsils and velum. Tuberculosis of the lymph-glands was associated with tuberculosis of the tonsils in 2 cases, and in one retropharyngeal abscess was observed. Bacilli were found in all cases, and in 2 cases, masses of tubercle bacilli were found. In 1 case, beside a unilateral tonsillar disease, there was a tuberculous infiltration of the corresponding vocal cord, which was probably secondary. Histologically (a) the chronic nonulcerative form, and (b) the milary type were represented. [J.H.W.R.]

Vaccination in Cuba, under Centralized Direction.—V. de la Guardia⁵ recalls the epidemic of variola in Havana of 1887 and 1888, when 2,255 deaths occurred among 20,000 cases. At the present time there is no case in the whole island. Successful vaccination, to the number of 300,000 have been attended to by the central bureau of vaccinations, and there is yet to hear of an instance of injury resulting from them. Special circulars have been drawn up addressed to "fathers of families." These, with a pamphlet, or set of sheets, explaining the value of vaccination done in youth, and at regular intervals thereafter, are freely distributed throughout the Republic. Glycerinated, animal lymph is employed by preference, and given without charge to any responsible person making request. No failures to "take" are reported in first instances. Conditions in other countries are cited, especially those of England and Germany, where compulsory vaccination is required. [T.H.E.]

EDITORIAL COMMENT

Epidural Injections.—In connection with the subject of the subarachnoid injection of cocain as a means of causing anesthesia, we recently took occasion to point out that the dangers of this method are sufficient to condemn it in the minds of cautious people, or of those, at least, who have not a strong craving for scenic effect. But there is a similar operation, sprung directly from the first, which is thought to be tolerably free from objectionable features, and indeed to have some distinct advantages. By its originator, Professor Cathelin, of Paris, it is called the epidural injection, the solution of cocain being placed exterior to the dura mater or around it.¹ Thus the injection might be better called peridural. The point for its introduction is in the median line of the sacrum just above the level of the sacrococcygeal ligament. As the spot is obviously not easy to find, a specialist gives us minute directions in this particular: The crest of the coccyx is followed till we reach the level of the sacrococcygeal ligament aforesaid; then "continuing the course upward we suddenly feel a hard, osseous protuberance, formed by the terminal portion of the crest of the coccyx below which the needle is to be inserted." The needle is first inserted on a line perpendicular to the integument, then on reaching the sacrococcygeal ligament, its direction is changed to a parallel with the sacral canal; the point of injection is attained when the resistance of the ligament is passed. All this requires considerable skill. The patient should be placed on the left side, with the thighs drawn up upon the abdomen to bring into view the bony protuberances. A preliminary injection of cocain is given to render less painful the complete insertion of the needle. Nevertheless the anatomic difficulties are formidable. If it were not for the evident practical difficulties, this operation would be a commendable innovation in the cases for which it is specially designed, *e. g.*, in sciatica, multiple neuritis, the pains of rheumatism and of tabes, etc. Giving all due importance to these difficulties of awkwardness and delay, it must be admitted the anesthesia produced is eminently satisfactory, since the solution of cocain comes in immediate contact both with the anterior and posterior roots of the sacral nerves, inducing as a secondary effect a state of insensibility, or diminished sensibility, in the extension of those nerves, and consequently a condition of painlessness throughout the lower extremities. A result thus obtained without any symptoms of meningitis or cocainism is certainly worthy of some degree of attention, if not approbation, from the medical profession. But it must be noted that the sensibility of the skin is little, if at all, impaired, and, that for purposes of major surgery, this kind of anesthesia is not sufficiently profound. On the other hand, its prolonged duration, which seems well established by the evidence, should make it a remedy of distinct advantage in that tedious and troublesome malady, sciatica, and possibly in other painful affections of the lower segment of the body. For procuring a painless "accouchement"—the dream of French surgeons—its claims must seem somewhat preposterous, as it is in itself a complicated and painful proceeding.

REVIEW OF LITERATURE

Excision of the Scapula for Progressive Chronic Interstitial Myositis, Associated with Obliterating Endarteritis.—W. B. Hopkins² reports the case. A colored boy 8 years of age, 2 months before admission to the hospital had fallen on his left shoulder. An abscess followed the con-

tusion, and pointed near the summit of the shoulder. It reopened a few days after healing and a sinus persisted which discharged freely and communicated with what appeared to be a carious scapula. A month later a mass of almost bony hardness began to develop over the body of the scapula and a skiagraph taken at that time indicated that the mass was in part at least composed of bone. Four months later, the mass having continued to grow, the child was etherized and the scapula excised. Preparatory to the excision an exploratory incision was made, a fragment of the mass removed and the histologic examination of the frozen section led to the conclusion that the growth was sarcoma. Operation was done after the method of Ollier. All of the tissues overlying the bone, except the integument, being removed. The only detail of the procedure that may be mentioned, was the easy arrest of hemorrhage obtained by getting perfect control of the bone with heavy lion-jaw forceps. The child made an uneventful recovery, there being moderate suppuration for a time and the wound closed permanently. An examination of the growth subsequently made, proved that it was not sarcoma but a progressive chronic interstitial myositis associated with obliterating endarteritis. An extensive bibliography is appended to the report. [A.B.C.]

Surgical Treatment of Diseases of the Stomach.—A. VanderVeer,¹ from the study of a number and variety of operations upon the stomach, reaches the following conclusions: 1. Gastroenterostomy can be applied to all kinds and conditions of stenosis at the pyloric end of the stomach. 2. In many cases it is an operation preferable to that of resection of the stomach, the immediate mortality being less and the possibility of extension of life being quite as great, with as much comfort. 3. Next to gastroenterostomy the most reasonable and satisfactory operation is gastrectomy, but this procedure must necessarily be limited to a few cases. When it is done, great attention should be paid to the removal of the lymphatic glands as in this rests much of the permanent success of the operation and nonreturn of the malignant growth. [A.G.E.]

I. Tubage of the Pharynx for Facilitating Anesthesia and Preventing the Inhalation of Blood in Operations on the Mouth and Face. II. Hot-water Bed for the Operating Table.—George W. Crile² states that 2 difficulties are encountered in operations about the mouth and face—the prevention of the inhalation of blood, and the even administration of the anesthetic. He has practised the following plan with success. The patient is completely anesthetized, the pharynx is then cocaineized, 2 drainage-tubes as large as possible are passed through the nares to the level of the epiglottis. The tubes are then severed at an equal distance from the nose. The mouth is well opened and the tongue drawn out, and the entire pharynx is then packed with rather large pieces of gauze. If thoroughly done, the base of the tongue is carried well forward and an air chamber, with which the rubber tubes and pharynx communicate, is thereby formed, the anesthetic is administered entirely away from the field of operation. Patient may be placed in any position desired without interfering with the anesthetic, and all blood prevented from passing backward in the pharynx and gaining access to the air passages. It is particularly adapted for operations of cleft palate and any other operations about the nose, face, and mouth. The author, in the same article, describes a hot-water bed which he has devised for the operating table, to prevent undue exposure to cold on the part of the patient. It is so arranged that it may be directly connected with the hot-water faucet, and the water allowed to flow through at any temperature desired. He has found, however, that one thorough heating of the table with the hot-water bed left in position, will answer for any ordinary operation. [A.B.C.]

Pathology and Treatment of Prostatic Obstruction.—W. B. Clarke³ recounts 33 operations for the removal of the hypertrophied prostate. He again raises the question as to whether in the so-called extirpation of the prostate the entire gland is removed. He believes that in certain instances he has removed the entire organ. He was convinced of this, because after having shelled out the enlarged mass by the suprapubic

¹ E. Marquès: Injections épidurales de cocaïne, Bull. de la Soc. Sc. et Méd. de l'ouest, t. xii, No. 1.

¹ Albany Medical Annals, October, 1903.

² Annals of Surgery, June, 1903.

³ British Medical Journal, July 4, 1903.

route, he found he could get his finger down as far as the triangular ligament and no trace of prostatic tissue could be detected, and further when the patient was restored to health a digital rectal examination failed to discover any remains of the organ. He details at some length his 33 cases, and says there are 2 main propositions to which he directs attention. The first of these is in relation to the varieties of prostatic obstruction, and the second is about the indications to be laid down for operative procedures. With the reduced mortality there is no reason why the operation should not be more general. In his 33 cases he lost but 3, or a mortality of 9% from the operation, and these were among his earlier cases. He believes the mortality will be still further reduced; if so, there is no reason why the condition known as catheter life should not in the main disappear. To some it is only an inconvenience, but these are few compared with the number who would gladly return to the more youthful habits of micturition, even could it be done as the result of an operation. [A.B.C.]

Primary Typhoidal Perforation of the Gallbladder.—J. F. Erdmann¹ reports the case of a woman of 46. The author states that primary in the sense here used has reference to cases in which it is positively demonstrable that the ulceration and perforation began within the gallbladder. She passed through a typhoid prodrome, which was followed by a 5 weeks' course of unquestionable typhoid fever. On the second day of the sixth week she was allowed to sit up in bed. On the night following she was seized with severe pain in the abdomen, pulse rose to 120, respiration became rapid, and the temperature 102°. There was some abdominal distention, tenderness, and the general symptoms of perforation. Exploration was done by a median incision through the right rectus. Fully a pint of bile-stained fluid was sponged out of the abdominal cavity and the intestine thoroughly inspected. When the gallbladder was exposed there was found an opening, irregularly circular, $\frac{3}{4}$ cm. ($\frac{1}{2}$ in.) in diameter. This was in the lower and inner aspect of the viscus near the cystic duct. There were no inflammatory manifestations on the external aspect of the gallbladder. Cholecystectomy was done, and the abdominal wall closed with drainage. A perfect recovery was recorded within 3 weeks. Upon opening the gallbladder 2 very small stones were found, the mucous membrane presented numerous small ulcerations. The opening passed obliquely through the gallbladder wall and gave a reverse picture of the funnel-shaped perforating ulcer usually seen. Cultures taken showed colon and typhoid bacilli. The author was able to find in literature 33 other cases of perforation of the gallbladder. He states there can be no question as to the wisdom of operative procedure in such cases. Of the 7 cases operated upon, 4 recovered, while in 27 cases not operated upon all died. The treatment in perforation of the gallbladder may be summed up in one word—cholecystectomy. [A.B.C.]

Desirability of Operating for Chronic Pancreatitis.—W. Hale White² says chronic pancreatitis with enlargement may arise from longstanding venous congestion, such as we see in nutmeg liver and in the large, tough kidney associated with cardiac disease; from alcoholic drinks, according to Kippel, Lefas, and Opie; from obstruction to the ducts of the organ, which may arise from pancreatic or biliary calculi or a tumor; rarely from tuberculosis and syphilis. None of these, at least so far as pertains to the pancreas, can be diagnosed with any degree of certainty. There is a form of chronic pancreatitis associated with jaundice, concerning the diagnosis of which we are not so completely at sea. It may possibly owe its existence to previous gallstones, but it is now generally believed to arise from an infection and inflammation extending by way of the ducts, to the pancreas; or it may, in certain cases, be due to a local peritonitis over the head of the pancreas. Robson and Moynihan mention the symptoms briefly, as deep jaundice, pain, tenderness, vomiting, and wasting; and the same authorities state that chronic pancreatitis must be treated by drainage of the gallbladder. White does not wholly agree to this method of treatment, and mentions a case which completely recovered after mere laparotomy. He believes the condition must be very rarely fatal, even without operation. [A.B.C.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

EDITORIAL COMMENT

The Influence of Growth on Late Hereditary Syphilis.—Leaving aside the influence exercised by growth on syphilitic infection and on hereditary syphilis appearing shortly after birth, we would consider particularly a certain form of the disease, whose study is most delicate and difficult, while its evolution is intimately related to growth; we refer to late hereditary syphilis.

The influence of late hereditary syphilis consists in these singular delays, or arrests of physical development. The subjects, who are hereditary syphilitics, are oftentimes remarkable from the fact that all the acts of organic evolution and of growth appear in them to be accomplished slowly and with difficulty, often remaining incomplete. They grow slowly and only develop insufficiently, remaining more or less inferior to the normal standard. In them virility is slow in becoming accentuated, the testicles remaining small for a long time; menstruation only appears at about the age of 17 or later, so that by the exiguous condition of their build, by the general delay occurring in their development, sometimes also by their stunted growth, the subjects in question deceive us as to their age.

Thus Fournier expresses himself on this subject, and it seems impossible to better or more concisely depict the reciprocal influence of growth and syphilis. Considered in its relation to nutrition in general, the part played by syphilis becomes preponderant in the hierarchy of causes modifying the individual and his descendants. Syphilis has a very powerful action on the organism, not only in producing denutrition, but it is also capable of causing an arrest in the development, a dystrophy, in other words, a complete degeneracy of the individual, as well as a degeneration of his race. And still more, syphilis does not simply produce its proper lesions, but it also causes a general perturbation in the organism, and this influence frequently shows itself in the form of divers organic changes, which are in no manner specific. This is one proof more which tends to show that, beside the specific action, which may only be transitory, there is still another dependent upon this cause, but which has a more powerful and durable action, because it is quite capable of changing the temperament, and even the constitution, not merely of those whom it directly strikes, but also those who are derived from the former. This cause is essentially a change in the modality of nutrition, although it cannot be denied that the means which are at our disposal at the present time are insufficient to allow one to chemically qualify it, but clinically it possesses its individual anatomy, for it always makes itself known by the same manifestations. Thus from syphilis, we frequently meet with those varied constitutional conditions, derived from specific infection, such as anemia, asthenia, neurasthenia, and various neuroses. In other instances, syphilis is the undeniable source of various affections, having very different pictures, such as scrofula, lupus, tuberculosis, and rickets; it also produces divers dystrophies, malformations, and arrests in the general development of the individual. Although of utmost interest, it would require too long consideration were we to study each system and each organ attacked and influenced by syphilis and growth. The former has a very marked predilection, for the skeleton, and the osseous tissue receives the first favors of the disease. The tibia, more especially, is given the trade-mark of specific infection, and is, by all odds, the guiding stone of hereditary syphilis. The development and growth of this bone is completely abnormal, presenting hyperostoses and bosses on its surface while an apparent pseudorachitic curve takes place. When one takes into consideration the hereditary syphilitic lesions of the bones, one cannot help being struck by their resemblance to those observed in rickets. Parrot upheld that both diseases originated from the same cause, and he distinctly formulated his thought when he said that rickets was only a manner by which hereditary syphilis made its presence known

at about the second year of life. This doctrine has been attacked with violence and injustice, and although Fournier has not admitted Parrot's views, he believes that rickets is far more frequently met in subjects of hereditary syphilis, while Taylor and Cazin admit that syphilis produces rickets by causing a disturbance of the nutrition, but deny its specific action. From a fairly large number of personal cases we would unhesitatingly admit the intimate relationship between syphilis and rickets, according to the latter views, in that it produces a dyscrasic nativity which predisposes the subject to morbid processes, which result from an insufficient vitality. Growth is a tributary to syphilis in a large number of the latter's manifestations, but to enter into a detailed account would extend beyond the intended limits of this notice, and we have consequently limited ourselves to these few considerations of general pathology.

REVIEW OF LITERATURE

Gummatous Affection of the Female Urethra.—G. Löwenbach¹ details 28 cases of this affection. It is unusually chronic and refractory to treatment. It starts in the region of the urethral orifice in the form of an ulcer of variable size, with hard, infiltrated, circumscribed edges, and a smooth, shining base. Later the ulcer may become serpiginous and be surrounded by edematous tissue. This stage may be of long duration. A more or less permanent hypertrophy usually results, amounting often to a tumor of considerable size, or a condition of elephantiasis. The mucous membrane of the urethra may be involved in the ulcerative process, with resulting strictures. The process may extend to other parts of the genitalia. This gummatous affection is a late manifestation of syphilis, coming on usually about 5 to 7 years after the primary infection. Subjective symptoms are very slight. The histologic picture is that of gummatous new formation, syphilitic vascular disease, and consecutive ulceration or fibrous metamorphosis. This affection has frequently been described under other names, such as chronic or elephantastic ulcer, rodent ulcer, ulcerative elephantiasis, lupus of the vulva, etc. The author gives a complete review of this literature. [B.K.]

Occurrence of Typhoid During Pregnancy.—A noteworthy increase of enteric fever is recorded in Rome, especially among pregnant women. Pic Masetti² writes on the management of this complication, and reports an instance in which artificial abortion was indicated, after alarming rise of temperature, weakness and rapidity of pulse, and uncontrollable continued vomiting. He quotes from a recent contribution to this subject by Tito Gualdi.³ Observers agree that pregnancy is no bar to typhoid infection, but apparently may predispose to it. Rokitsansky and Niemeyer dissent; yet their views were expressed before collation of recent information. Until the present time little attention has been given to microorganismal infection of the fetus. However, it is known that the placenta is no effective bar. Chantemesse, Widal, and Eberth have discovered the specific bacilli in blood derived from a fetus taken from a typhoid patient. Transmission may be vascular, or may have origin in fecal or urinary discharge at the vaginal orifice and ascent of the germ through the genital tract to where the seclusion of the fetus gives but imperfect safety. Masetti unites with Gualdi in bearing testimony to the frequency of fetal infection. Death of the fetus may occur from simple elevation of maternal temperature, or from the specific fever. Doléris and Doré find this a source of premature uterine contraction. In addition, toxic materials circulating in the blood, especially if of typhoid origin, increase the danger of abortion and relatively darken the general prognosis. Abortion takes place most frequently during the second week of the fever, and occurs in about two-thirds of the cases. Its occurrence is not necessarily of unfavorable effect on the febrile attack. After an initial rise the temperature may break. Treatment of enteric fever complicated by pregnancy will follow accepted lines, even to the regular Brand procedure. The reduction of tem-

perature will lessen the danger of abortion, and the cold baths are of advantage in their effect on the nervous system. One constant danger of typhoid complication is the appearance of pernicious vomiting, as in the case above quoted. When abortion occurs, or is induced, extreme care must be taken to remove the entire fetal membranes. Abortion is a necessity if renal involvement supervenes, or in the event of very difficult nutrition of the patient, or the occurrence of pernicious vomiting to which the typhoid infection seems to predispose. Finally, the general opinion as to the frequency of typhoid infection of those pregnant is determined, but Niemeyer and Rokitsansky believe it due to the lowered lymphatic and vascular resistance, and especially a reduction in hemoglobin. [T.H.E.]

Maternal Pelvis and Fetus.—C. A. Lane,¹ of London, makes a clinical comparison of the maternal pelvis and of the pelvis in Europeans, Eurasians and Bengalis, gives 7 tables showing various comparative measurements of fetal heads, maternal pelvis, etc., and sums up his conclusions in the form of a law stated thus: "The child grows in utero in such a manner and at such a rate that at full term his size is proportional to that of the mother's pelvis through which he has to pass in order to be born." This hereditary influence appears to have a far greater share in determining the size of the child than any of the causes commonly recognized. [W.K.]

Tumefactions of the Climacteric Breast.—T. A. McGraw² says that for many years he advised his students to operate at once on all tumefactions of doubtful character in the breasts of women over 30. This advice was prompted by the many cases of neglected, and hence incurable, cancers brought to his notice. He has during later years become convinced that this teaching needs to be materially modified. His experience seems rather unusual, though none the less gratifying, as he states that of late years the experience of his earlier professional life has been so reversed that where formerly he mourned over lives lost from delay he is now more often obliged to dissent from the advice of physicians who send cases of benign conditions diagnosed as cancer. McGraw sees an evil in the too unfavorable diagnoses in doubtful cases in that the growth may be benign and the patient will be relieved by a quack who gets, or takes, the credit for curing a cancer. The use of the exploring needle in doubtful cases is believed to be far less frequent than it should be. Involution cysts usually disappear after puncture but McGraw has seen 1 or 2 cases which have been the forerunners of cancer. [A.G.E.]

Spontaneous Healing of a Vesicocervical Fistula.—Gallatin³ reports the case of a woman who had given birth to 7 children, the first delivery alone being normal; the other 6 were all dead—1 through craniotomy, 2 by perforation, the rest dying during forceps delivery. At the end of the eighth pregnancy the patient entered a hospital, hoping to have a living child. It was, however, found necessary to deliver the child with forceps, and it was asphyxiated with the navel cord wound twice around its neck. Resuscitation was found impossible. Subsequent examination of the patient proved the existence of a cervicovesical fistula which allowed the urine to pass out through the vagina. Severe hemorrhage prevented the suturing of the fistula at the time, and Gallatin had to be satisfied with an injection of ergotin followed by daily irrigation with boracic acid solution. In about 10 days the patient emptied the bladder normally, showing the spontaneous healing of the fistula. A subsequent pregnancy ended with uterine rupture, laparotomy, and final recovery. [W.K.]

The Present Position of Hysterectomy for Fibroids.—Skene Keith⁴ believes that the real reduction in the death-rate has been obtained by the systematic discarding of the clamp and serre-nœud, the extraperitoneal operation, and the adoption of the intraperitoneal treatment of the neck of the uterus or complete hysterectomy. His practice is at present rather in favor of leaving the cervix, perhaps because he has done it more frequently, and also because it appears to him to be more quickly and easily performed. The operation of election may come to

¹ Zeit. für Heilkunde, 1903, Bd. xxiv, Heft 1 and 4; Abth. f. Path., Heft 1 and 2.

⁴ American Gynecology, June, 1903.

be complete removal. In a patient of 50, the symptoms must be severe to justify hysterectomy. In the following cases hysterectomy ought to be the rule: In all fibrocysts, in all edematous tumors when accompanied by profuse watery discharge, in all large tumors causing symptoms, and when the patient is under 50. Even when a patient is over 50, it may be advisable to remove a tumor of 30 pounds or 40 pounds. In small tumors extending as high as the umbilicus or so, fibrocysts and edematous tumors excepted, as a general rule he advises Apostoli's treatment. [F.C.H.]

Operation for Cervical Myoma.—Gottschalk¹ describes with illustrations an operation for myoma of the cervix. The operation avoids all danger of injury to the ureters or much loss of blood. Because of the maximum inversion of the external coat of the mucous membrane and the exact suturing of the incision in the collum, the raw surface is reduced to small proportions, and through the firm internal and external tamponade of the uterus is brought to the minimum. Thus the danger of infection is lessened. The mucous membrane of the uterine cavity remains untouched and not only the body, but also the neck, of the uterus retains its functions. Since the operator does not come in contact with the bed of the tumor its asepsis is assured. [W.K.]

The Treatment of Uterine Fibroids.—A. H. G. Doran² discusses at some length the present position of our knowledge regarding the above question. He holds that a fibroid demands no immediate treatment when its sole symptom is its own existence, but the most quiescent fibroid requires watching. The physician must be very wary about the opinions of others, however authoritative they may seem. The experienced physician and the successful operator are never wholly free from bias, and hence tend to oppose each other. The surgeon rightly urges that the patient who has submitted to operation feels free from the burden of mental worry caused by the presence of a tumor. This burden is no fiction, but a successful operation means more than the restoration of mental comfort to the patient. The impossibility of calculating the future growth of a fibroid is put too much in the background by the advocates of hysterectomy. The gravest possibility from this operation is the advent of psychic disturbance. When a fibroid uterus is to be removed, the retroperitoneal variety of supravaginal hysterectomy is the best and simplest operation. Doran finds that the saving of a portion of the endometrium, that is to say, amputation above the level of the os internum, distinctly, though not very markedly influences in a favorable sense the catamenial functions. It is better to leave one ovary if it be healthy, but the advantages of conservative treatment of the ovaries has been exaggerated. [A.G.E.]

The Risks of Allowing Lactation and Pregnancy to Overlap.—H. M. Church³ has noted this overlapping in 3% of his private cases. Were a systematic investigation made, he believes it would be found that the suckling was or became a delicate child, that at some stage of his development he suffered from some affection of the nervous system, and that he was the mentally weak one of the family; that during lactation the embryo was prematurely expelled, or if it reached full time, that it in many cases did so with lowered vitality; and that the mother's health was generally undermined for a longer or shorter time. Cases in which the nursing suddenly and unaccountably declines the breast probably are those in which the mother has again conceived. Menstruation may have a similar but less marked effect. The lowering of the mother's health is the explanation of many a bad case of rickets, dwarfed stature, and bad teeth. The primitive dental groove forms about the sixth week of intrauterine life. Marked changes in the osseous and dental systems in the lower animals have followed simple change of diet in the mother during pregnancy. According to Daris, the milk in pregnancy assumes the nature of colostrum. In choosing a wet-nurse, one should be selected whose child is about the same age as the suckling with which she is to be entrusted, as from month to month the sugar steadily increases and the butter decreases. The author reports 9 cases illustrating the risks of the double drain. [H.M.]

TREATMENT

SOLOMON SOLIS COHEN
H. C. WOOD, JR. L. F. APPLEMAN

REVIEW OF LITERATURE

Another Salicylic Preparation.—Pfeiffer¹ reports favorable results with a new salicylic ester intended for external use, known as esterdermasan, its chemic composition not being clearly stated. He has found it of value as an anodyne in many painful conditions, including various forms of rheumatism, tabes dorsalis, arthritis deformans, etc. It is used in the following manner: 5 gm. to 10 gm. (1 dr. to 2 dr.) are painted on the affected region and covered with a dressing which is not fat absorbing. He believes that the local application is useful because of its stimulant effect on the skin and because it causes the action of the salicylate directly at the needed point. [H.C.W.]

The Results of Organotherapy in Addison's Disease.—E. W. Adams² tabulates the results in 105 cases of Addison's disease treated by organotherapy. The cases have been arranged in 4 groups: 1. Cases in which alarming or fatal results were presumably or possibly due to the treatment—7. 2. Cases uninfluenced by, or deriving but doubtful benefit from the organotherapy—49. 3. Cases in which marked improvement was coincident with treatment—33. 4. Cases in which permanent benefit (? cures) accrued apparently as a result of the suprarenal feeding—16. Tables are also given to show the progress of a number of the cases during the several methods of treatment, and the coincident progress of cardinal symptoms during the treatment. A table also gives the postmortem findings in the adrenals from 17 cases, in relation with the previous reaction of the disease to organotherapy. From a study of these cases Adams draws the following deductions: 1. There appears to be a certain class of cases of Addison's disease which derives indubitable benefit from the exhibition of some form of suprarenal substance, though in any given case it remains impossible to determine the probable response to the treatment. 2. In any given case of the disease, selected haphazard, the probability obtains that disappointment will follow the institution of organotherapy but that probability is very distinctly less than that attaching to any alternative method of treatment at present known. 3. The last word upon the preparation to be used and its method of administration remains to be said. The problem seems to be to get a sufficient and continuous dose of the pure and active principle unchanged into the blood stream. Intravenous injection is impracticable. [A.G.E.]

Empyroform.—Empyroform is a condensation product from tar and formaldehyd, occurring as a brown, nonhygroscopic powder with a peculiar odor, somewhat reminding one of tar. It is insoluble in water, but soluble in caustic alkalies and chloroform; on heating it liberates formaldehyd. Skarlek³ has found it useful in eczema. It lessens the itching, has marked drying properties, and is nonirritant. Unlike tar, it is useful also in the acute stages of eczema. He employs the following prescription:

Empyroform	} of each 25 gm. (6 dr.)
Starch	
Purified petrolatum 50 gm. (12 dr.)

In psoriasis or prurigo, it exercises no beneficial effect. [H.C.W.]

The Temperature of Nurslings.—In considering the superiority of breast-feeding over artificial feeding, M. Weill⁴ calls attention to the fact that in infants nourished from the breast the temperature remains at 98.6° F., without oscillation. On the contrary, in infants fed on cows' milk the temperature curve shows variations of .3° or .4° between morning and evening, the evening temperature being the higher. When the child is fed on asses' milk the temperature varies to a lesser degree. When a child who has been nourished on the breast is given feculents or asses' milk, the temperature oscillates slightly. This demonstrates that the nutritive changes are perfect in a child nourished at the breast, and defective in children nourished artificially. [L.F.A.]

Citarin.¹—Citarin is a new formaldehyd preparation formed by the action of formaldehyd on sodium citrate. It is recommended as a uric acid solvent. The dose is 2 gm. (30 gr.) 3 or 4 times a day. [H.C.W.]

The Nature and Treatment of Hay-fever.—Dunbar has isolated a toxin from the pollen of the graminaceae, which he recognized as the cause of hay-fever. It is an albuminoid contained in the innermost part of the starch grain of the pollen. The pollen is dissolved with ether, and the toxin precipitated with alcohol. When injected into the arm of an individual predisposed to the disease even in winter time, the typical symptom-complex of hay-fever was produced, while others not predisposed were not affected. A. Thost² injected the toxin into animals, producing a serum in the usual manner, which acted as an antidote to the poison; when a mixture of the two was injected into ordinarily susceptible people no symptoms were produced. The serum also acted as an immediate curative agent in people affected with the symptoms brought on by the prepared toxin. It will be employed at the earliest opportunity in cases of true hay-fever. In the meantime it will serve to differentiate true and false hay-fever. [E.L.] [Since this abstract was prepared, experience has shown Dunbar's serum to have a limited and uncertain value in controlling and relieving various forms of hay fever, but the method merits development. S.S.C.]

Treatment of Osteitis Deformans and Osteoarthritis.—Peckham³ has had very surprising results in the treatment of this disease by blistering around the diseased joints. He reports 5 patients almost cured by the treatment. [H.C.W.]

Method of Removing Collargol Spots.—H. Robert⁴ gives the following means of removing collargol spots from white cloth: First dip the stained cloth in the following solution until the spot disappears:

Bromin	5 gm. (80 grs.)
Water	500 gm. (1 pint)

The cloth should then be rinsed in pure water. After this procedure, the black spot is often replaced by one of pale yellowish-green color, due to the formation of silver bromid. In order to make this second spot disappear, it is necessary to dip it in a solution of:

Sodium hyposulfite	150 gm. (5 oz.)
Water	500 cc. (1 pint)

This dissolves the silver bromid, and the cloth is then rinsed in pure water. [L.F.A.]

Intravenous Injection of Colloidal Silver in Puerperal Septicemia.—Rosenstein⁵ has had good results with the use of soluble metallic silver (collargol) by its intravenous administration. This medicament was originally recommended by Credé in the form of an ointment, the idea being that the silver would be absorbed through the skin and exercise an antiseptic action. It has been abundantly shown that colloidal silver as ordinarily employed in septicemia cannot do good through its antiseptic influence, since it has practically none. Rosenstein points out that good results in various forms of septic infections have been obtained both in human and veterinary medicine by the use of this remedy. He believes that its intravenous injection is the more rational mode of administration, since the ointment must be absorbed through the skin slowly and in uncertain quantities, and since the hypodermic use is too painful for ordinary application. He injects by means of a special syringe, 5 gm. (75 gr.) of colloidal silver in 2% solution in a vein of the arm. [H.C.W.]

Antistreptococcal Serum and Its Use in Man.—Menzer's⁶ experiments lead to the following conclusions: 1. As in animals, so in man, the antistreptococcal serum acts by producing phagocytosis; therefore, the human organism must do the major part of the work in the fight with streptococci. If the organism is too weak, the employment of the serum is useless. 2. The organism must destroy the bacteria and absorb them, as well as the destroyed cells. In encapsulated pus collections the

serum is counterindicated without surgical assistance; it increases the absorption of pus toxins. 3. In acute streptococemia it is very useful, if given in large doses; in chronic streptococemia if given in doses suitable to the individual case. 4. Only such serums are useful in human streptococcemias, which have been derived from human streptococci. 5. The curative effect on man cannot be proved by trying the serum on animals. Its action on man is the only criterion. [E.L.]

Poisoning Due to the Chemic Decomposition of Bromoform.—A. L. Oberdorfer¹ relates the history of a child of 4½ years, who was under treatment for pertussis. Five drops of bromoform had been given 3 times daily for a week, and the order repeated for the second week. On the second day of that week, just after a dose of the bromoform, the child rather suddenly became comatose with rapid and feeble pulse and stertorous breathing. The breath smelled of bromin, and an attempt was made to wash out the stomach. The introduction of the tube was followed by such failure of the pulse and cyanosis that it had to be abandoned. Symptoms, especially cyanosis, were alarming at times, but consciousness began 15 hours after the attack. In a few days the child was in its usual health. Examination of the bottle from which the bromoform had been taken, showed the remaining fluid to consist of 2 well-defined layers. The lower one was of a muddy color, the upper one more transparent and of an oily, viscid consistency. A chemic analysis showed it to consist of free bromin and hydrochloric acid. As an overdose had not been given, it is supposed that the decomposition was responsible for the effect. Even then the explanation is not entirely satisfactory on account of the small dose and the obscure chemistry, but the case is of importance as indicating a possible danger from the drug. [A.G.E.]

Emulsion of Brain in the Treatment of Tetanus.—Krokiewicz² reports 4 cases of tetanus treated by the injection of an emulsion of rabbits' brain. He has collected 12 cases beside his own, in which this method was employed. Out of these 16 cases there were but 3 fatal results, although at least 8 of them could be reckoned as severe infections. In this treatment an emulsion of the entire brain of 1 rabbit is injected subcutaneously at intervals of one or more days, the highest number of injections given in any individual case being six. Other treatment need not be interrupted. [H.C.W.]

FORMULAS, ORIGINAL AND SELECTED.

Local Application for Ivy Poisoning.—

Sodium hyposulfite	30 gm. (1 oz.)
Menthol	0.3 gm. (5 gr.)
Alcohol	4 cc. (1 dr.)
Spirit nitrous ether	30 cc. (1 oz.)
Distilled water, enough to make	500 cc. (1 pt.)

Dissolve the soda salt in the water and the menthol in the alcohol. Mix the 2 solutions and filter. Apply freely to affected parts with soft sponge.—[Med. Pharm. Critic and Guide.]

Alopecia Areata.—Herxheimer³ recommends:

Oil of cotton root	2 gm. (30 gr.)
Tincture of benzoin	20 cc. (5 dr.)
Spirit of lavender	40 cc. (10 dr.)
Alcohol	40 cc. (10 dr.)

[H.C.W.]

Local Application for Gouty Joints.—

Sodium carbonate	12 gm. (3 dr.)
Tincture of opium	60 cc. (2 oz.)
Belladonna liniment	60 cc. (2 oz.)
Water, to make	250 cc. (8 oz.)

Mix with equal parts of hot water, and saturate a cloth with the mixture; apply while warm over the affected joint, and cover with oiled silk. [H.C.W.]

Sodium Ethylate for Warts.—This is said to be quite effective. It should be applied with a glass rod and reapplied when the scab that has formed falls off. Care must be taken not to bring the sodium ethylate in contact with water, as it may take fire with disastrous consequences.—[Med. Pharm. Critic and Guide.]

Acute Gout.¹—

Magnesium sulfate	6 gm. (1½ dr.)
Magnesium carbonate	2 gm. (30 gr.)
Potassium citrate	2 gm. (30 gr.)
Tincture of colchicum seeds	0.6 cc. (10 m.)
Peppermint water, to make	30 cc. (1 oz.)

Repeat every 3 hours until the bowels become loose.

[H.C.W.]

Ewald's Laxative Powder.—

Pulv. rhubarb	20 parts
Sodii sulf. exsic.	10 "
Sodii bicarbonatis	5 "

—[Med. Pharm. Critic and Guide.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended December 26, 1903:

SMALLPOX—UNITED STATES.			Cases	Deaths
California:	San Francisco.....Dec. 6-13.....	2		
Illinois:	Belleville.....Dec. 12-19.....	2		
	Danville.....Dec. 12-19.....	1		
Indiana:	Evansville.....Dec. 12-19.....	3		
Louisiana:	New Orleans.....Dec. 12-19.....	3

Changes in the Medical Corps of the U. S. Army for the week ended December 26, 1903:

PAGE, Captain HENRY, assistant surgeon, will report to the commanding general, department of Luzon, for assignment to duty.

RICH, First Lieutenant EDWIN W., assistant surgeon, will report to the commanding general, department of Luzon, for assignment to duty.

ARWINE, JAMES T., contract surgeon, leave granted, is extended ten days.

HOLLORAN, First Lieutenant PAUL S., assistant surgeon, is relieved from duty at Lucena, Tayabas, and will report at Convalescent Hospital, Corregidor Island, for duty, relieving First Lieutenant Robert L. Carswell, assistant surgeon, who will proceed to Zamboanga, Mindanao, reporting to the commanding general, department of Mindanao, for assignment to duty.

PATTERSON, First Lieutenant ROBERT U., assistant surgeon, is relieved from duty at Camp Vicars, Mindanao, and will proceed to Manila, reporting to the commanding officer, First Reserve Hospital, for duty.

BAILY, HOWARD H., contract surgeon, is granted leave for one month, with permission to visit the United States, and apply for an extension of two months.

QUINTON, Captain WILLIAM, assistant surgeon, is relieved from duty at Lucena, Tayabas, and will proceed to Iloilo, Panay, for assignment to duty.

STONE, FRANK P., contract dental surgeon, is granted leave for one month, upon surgeon's certificate, with permission to leave the limits of the department of California.

CHAMBERS, WILLIAM H., contract dental surgeon, is granted leave for twelve days, to take effect from December 22.

USHER, First Lieutenant FRANCIS M. C., assistant surgeon, is granted leave for one month.

JOHNSON, Major RICHARD W., surgeon, will proceed from Washington, D. C., to St. Louis, Mo., and take station for duty pertaining to the exhibit of the medical department of the Army at the Louisiana Purchase Exposition.

CARROLL, First Lieutenant JAMES, assistant surgeon, is detailed to represent the medical department of the Army at the meeting of the Society of American Bacteriologists to be held in Philadelphia, Pa., December 9 and 30.

SNYDER, CALVIN D., contract surgeon, now at Baltimore, Md., will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands.

So much of orders of November 21 as directs the commanding officer, company of instruction No. 2, hospital corps, Fort McDowell, to send Sergeant First Class Gustav Knapp to the Philippine Islands is revoked. Sergeant First Class Knapp will proceed to Ord Barracks, Monterey, Cal., for temporary duty.

ALLEN, First Lieutenant JOHN H., assistant surgeon, having reported his arrival at San Francisco, Cal., is relieved from further duty in the division of the Philippines, and will report for duty at the United States General Hospital, Presidio, to relieve First Lieutenant W. C. Chidester, assistant surgeon. Lieutenant Chidester will proceed to Fort Lawton for duty, to relieve Contract Surgeon Wallace E. Sabin. Contract Surgeon Sabin will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands on transport to sail from San Francisco about February 1.

WILLIAMS, ADRIAN D., contract surgeon, now at Brooklyn, N. Y., will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands.

HARTNETT, First Lieutenant EUGENE H., assistant surgeon, is granted leave for fourteen days.

FORD, Captain JOSEPH H., assistant surgeon, is relieved from duty at the United States General Hospital, Washington Barracks, to take effect upon the arrival of First Lieutenant William H. Brooks, assistant surgeon, at that hospital, and will then proceed to Fort Reno to relieve First Lieutenant Charles W. Farr, assistant surgeon. Lieutenant Farr will proceed to Fort Mason for duty.

EKWURZEL, First Lieutenant GEORGE M., assistant surgeon, is relieved from temporary duty at New Haven, Conn., to take effect upon the return to duty at that place of First Lieutenant Wallace De Witt, assistant surgeon, and will then proceed to Fort Trumbull, to relieve Captain James R. Church, assistant surgeon. Captain Church will proceed to Fort Brown to relieve Contract Surgeon Jos. K. Combe.

PASCOE, JAMES B., contract surgeon, now at San Francisco, Cal., will report to the commanding general, department of California, for transportation to the Philippine Islands.

MILLER, DANIEL R., sergeant first class, now at the Army General Hospital, Presidio, will proceed to Fort Trumbull for duty.

HARTSOCK, First Lieutenant FREDERICK M., assistant surgeon, is granted leave for ten days from December 23.

HICKS, GEORGE W., sergeant first class, Alcatraz Island, Cal., will proceed to Manila, P. I., on the government transport sailing from San Francisco, Cal., about January 1.

BAIRD, JAMES W., sergeant first class, Presidio, will proceed to Alcatraz Island, Cal., for duty.

WAGNITZ, EDWARD J., sergeant first class, office of the chief surgeon, department of California, San Francisco, Cal., will proceed to the Presidio for duty.

Changes in the Medical Corps of the U. S. Navy for the week ended December 26, 1903:

McCLURG W. A., medical inspector, ordered to the Bureau of Medicine and Surgery, Navy Department—December 18.

JOHNSON, M. K., surgeon, detached from the Naval Hospital, New York, N. Y., and ordered to the Tacoma—December 18.

SCHWERIN, L. H., acting assistant surgeon, detached from the Southern and ordered to the Abarenda—December 19.

SPRATLING, L. W., surgeon, detached from the Hancock and ordered to the Navy Yard, New York, for special temporary duty at the Naval Laboratory—December 21.

CARPENTER, D. N., surgeon, detached from the Naval Hospital, Washington, D. C., and ordered to the Dixie, for duty with the Panama marine brigade—December 23.

SPRATLING, L. W., surgeon, detached from the Naval Laboratory, Brooklyn, N. Y., and ordered to the Dixie, for duty with the Panama marine brigade—December 23.

ANGERY, G. L., passed assistant surgeon, detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Dixie, for duty with the Panama marine brigade—December 23.

JANUARY 9, 1904.

\$5.00 YEARLY.

False Vaccination Scars: A Vile Crime Encouraged.—In the latest issue of *Medical Talk for the Home*—an organ said to be maintained by the Peruna Company—there is an article which deserves the careful consideration of legislators, the profession, and the community. The writer and the publisher should be prosecuted to the full extent of the law if there is any law in Ohio that will authorize such prosecution. If none exists it should be enacted. The writer of this incitation to crime tells "how to produce a scar resembling vaccination," by means of nitric acid. The most nauseating part is that which advises against lying and making any pretense that the child has been vaccinated:

If a doctor wants to know whether the child has been vaccinated or not, simply show him the scar, and if he is satisfied with the scar well and good. I would not advise any physician to give a certificate of vaccination after having performed this imitation, because the deception would be simply a lie, and lying is not to be approved of even to escape the necessity of being vaccinated. My own children have been treated in this way, and have been examined a great many times in school for vaccination and the scars have always been regarded as genuine vaccination scars. Other children have been vaccinated in the same way, but I have always refused to grant a certificate to any one on account of this vaccination.

Here is a liar (and an editor who publishes the criminal's lie) who advises others to evade the law by committing lying and useless vivisection, and who then confesses that by it he has enacted the lie of deception many times and yet who in doing so counsels against lying and deception! All of which is an illustration of anti-vaccination ethics. These fellows need sharp looking after if the community is ever to be protected from the ravages of smallpox. One wonders how much of the vogue of the heresy has been due to the falsified statistics and the spread of the disease through the makers of "scars resembling vaccination."

The Conservation of Medicinal Plants.—The rapid destruction of the forests of the United States, especially in the eastern portions, with the consequent interference with the water supply, change in climate, etc., has for some years been a matter of serious concern to the thoughtful citizen. A recent article by Dr. Henry Kraemer¹ emphasizes an aspect of this question that is

of particular interest to the medical profession. This writer states that if the present rate of gathering of native herbs and drugs continues for ten years it is probable that our principal medicinal plants will be well nigh exterminated unless measures are taken either to conserve or cultivate them. Inquiries indicate that some of our wellknown plants are already nearly exterminated. Among these are spigelia, serpentaria, senega, and cyripedium. The possibility of improving plants by selection and cultivation, as has been done with coca and cinchona, is an incentive to their study, but of greater importance is a knowledge of the peculiar requirements of each, in order that they may be cultivated, if this should be necessary to ensure their perpetuity. The following classification is given: Cultivated medicinal plants in the United States, 190; wild indigenous or neutralized, 178; foreign plants that might be cultivated, 56; foreign plants uncertain as to cultivation, 75. This shows that approximately three-fourths of all medicinal plants are growing wild or in cultivation in this country, and that of the remaining one-fourth probably one-half could be grown here. The article in question is very pertinent and timely, and should be brought to the attention of not only physicians, but also nurserymen and the laity, who primarily must take the matter in hand.

"The Practice of Medicine," Again.—In criticism of the legal definition of the term a practitioner of medicine, recently given in *American Medicine*, several of the best class lay journals have shown a failure to understand the true bearings of the question at issue, and as the enactment and execution of all laws depends entirely upon the cooperation of the lay world, we feel a further word of explanation is necessary. That "the practice of medicine is the treatment of diseases, deformities, and injuries," is beyond question, but our lay critics say that this would debar help in emergency cases, the bandaging of a finger, the giving of household remedies, etc. The interest that every man, woman, and child must feel in health, limb, and life, forces the question as to whom the responsibilities of treating these belongs. To whose care are they to consign the diseased, deformed, and injured? The logical and only answer must be, to those "qualified." Can any one ignorant of the causes, nature, and natural history of human ills, treat intelligently any of these by any means whatso-

¹ American Journal of Pharmacy, December, 1903.

ever unless well grounded in the medical sciences? An answer is superfluous.

What then constitutes a legal practitioner of medicine? It is anyone licensed by any State to treat deformities, diseases, and injuries. Who are these? Only those whom statutory law compels by process of examination before the properly appointed officials, to *prove qualification*. No right minded citizen opposes this just requirement. Has anyone the right to assume the responsibilities attaching to so important a role who is not qualified? Whether one familiar with ills believes that prayer alone, or prayer with other means, is proper in a given condition, is not the right nor purpose of any law to govern. Exception is mistakenly made that a parent, grandmother, or preacher furnishing relief for any ill would be amenable to these statutes. Not at all so. All these emergencies can, under the definition, be met in ways best known to those to whom the conditions offer. A man run over in the street, or falling in an epileptic fit, or awakening in the night in pain, may be attended by any one at hand. This is a totally different matter from posing before the public as one *qualified to treat*, by any means whatsoever, diseases, deformities, and injuries. Such, as law very properly requires, must prove knowledge of the structure and function of the human body; of the causes, symptoms, processes, and consequences of diseases; of the disturbed relations of parts when dislocated, fractured and otherwise injured; of the signs and symptoms of these; of the physical principles involved in their readjustment and maintenance by proper apparatus; of the nature, physiologic actions, powers, and doses of drugs; of the unalterable law of cause and effect in epidemic and pestilential and contagious diseases; of the causes of these and the methods of prevention. To be "qualified" is to be learned in all this involves, and requires what the laws now demand—first, a liberal and general education, particularly in science; second, a well grounded and adequate knowledge of the art and science of medicine. These being possessed by every one who has the right to treat by "any means whatsoever" is what the definition of "the practice of medicine" vouchsafes. A legal practitioner is one whom the State licenses, and one who *assumes* the responsibilities to treat diseases, deformities, and injuries by offering his or her services so to do, unless *qualified*, should very properly, for the highest interests of fellow-man and community, be held responsible and amenable to that law which protects the health, life, and limb of fellow-beings from the fearful consequences of treatment, no matter by what means by those *not* qualified.

Mr. Bell's vindication of his proposed Congress on Tuberculosis, as was foreseen, follows promptly upon the criticism of the leading members of the profession, and their resolution to have nothing to do with it. It is characteristic, especially as regards grammatical, or rather ungrammatical usages, and must please—those whom it pleases. Very naturally the circular says that: "The only opposition that has thus far developed of any note has been from medical sources outside the membership of the body. The exception

has been so small as not to be noticeable, and to only verify the truth of the statement that the occasional exception seems only to prove the rule." "The supineness and inactivity of the medical profession in our country to grapple with the subject," is said to be the reason of "the urgent, immediate, and the paramount duty" of the great "lawyers, jurists, medical men, scientists, legislators," etc., to organize the International Congress—as they have done—"under the presidency of that Nestor of sanitation, Dr. A. N. Bell," etc. "It was most natural that our government should continue this splendid, this superb work along the same lines." The manufacture of vice-presidents and the gathering of political names and influences has been most zealously prosecuted, as is duly set forth in glowing and wonderful English. The appeal of inflamed vanity to hungry egotism by means of bombastic and ludicrous asseverations of the love of humanity and the awful self-sacrificing exertions of the faithful (to offset the negligence of the supine medical profession) would be amusing were it not for other considerations. Mr. Bell expressly emphasizes the fact that the medical profession is in no way responsible for his congress. For this the profession should evince proper appreciation.

A Novel Christmas Gift.—Every physician who has been in practice several years finds that many of his patients could not, or would not, at least, have not paid his bills for professional services. He remains undecided after many attempts to collect whether it is of any use to continue efforts, and to waste further postage stamps. One of our subscribers last Christmas day decided upon a unique method of therapeutics for this endemic financial disease. It seems a commendable plan at least of ending an irritating trouble in bookkeeping. Will it encourage the dilatory to seek for future holiday gifts by a method they have found effective? Our correspondent does not appear solicitous. He sent out about 500 letters worded as follows:

— — — — —, December 24, 1903.

— — — — —:—
The amount on my books against you is \$—, and, as you know, has been standing a long time. I have given you every opportunity to pay the account honorably, and, since I am unwilling to believe that you mean to be dishonest, I must conclude that you have failed to settle because you were unable to do so. This being the case, I take pleasure in informing you that I have this day forgiven the debt, and will ask you to consider it as a Christmas Gift!

Wishing you the compliments of the season, I remain,
Yours truly,
— — — — —.

The Eyes of School Children.—At the last annual meeting of the American Medical Association, the House of Representatives, on the recommendation of the Ophthalmologic Section, passed the following:

Resolved, That it is advised by the American Medical Association that measures be taken by the various school authorities and Boards of Education, Boards of Health, and if possible, State legislators, to secure examinations of the eyes and ears of all school children in this country, with a view to the suitable treatment for the relief of the ophthalmologic and otologic imperfections.

In accordance with this excellent advice, a leaflet (the first of its kind, if we mistake not) has been pre-

pared by the superintendent of public schools of Los Angeles, California, for the purpose of instructing teachers concerning errors of refraction, methods of examining the eyes, etc. The plan should be imitated in all of our schools, and be followed by measures looking to the actual carrying out of the suggestions made. There should be no attempt, of course, to make the teacher or the optician replace the oculist, but all the instructions to teachers should enable them to detect the subtle and easily overlooked causes of eyestrain and the varied and pernicious influence it has upon the pupil's general health, school attendance, and ability to study. It is strange how slow is the community, and especially the teacher, to recognize the importance of this factor in school life. It is not difficult for the teacher to learn the signs of eyestrain, and to make the few tests necessary to urge children and parents to consult the specialist.

"**Cereopathy**" is the latest addition to the pathic -pathies. According to the D. S. T. ("Doctor of Suggestive Therapeutics," under whose care a child in Philadelphia recently died of pneumonia), it is just like a multitude of other illustrations of the one disease called by as many different names. "Doctor" Brown, in answer to the Coroner's questions, said that he was a graduate of "the American College of Science," located in Philadelphia, and of the "College of Physicians and Surgeons of Rochester." Because he "gave no medicines," he did not know that he had to pass the State Board. He had been practising for two and a half or three years, but before that he was a carpenter by trade. Cereopathy, he explained, "is the new science of health, being a combination of nature's forces into one great system, to cure and to remain cured. It is that God-given element given to all people on earth to cure, when all other remedies fail, without drugs or the knife." When the carpenter studied his God-given new science, why the "colleges" that "graduated" him are allowed to sell diplomas, why these "graduates" are allowed to practise, and why treating the sick to death because not giving drugs is not practice of medicine—here are questions for the people and their law-makers to answer.

A Quack Compelled to "Move On."—Dr. J. A. Andrews, of Santa Barbara, Cal., has set an example to the citizens of quack-pestered cities which should be followed. In Davenport, Ia., the migrant's name was Dr. J. B. Palmer, but when he settled in Santa Barbara he became Dr. D. D. Palmer, and he filled the newspapers with reading notices, and sent to every house a seemingly limitless amount of wild trash concerning his world-redeeming and medical-profession killing new system, called "Cheiropactic." The silliness of this stuff was unimaginable, but the worse, apparently, such claptrap is, the more foolish people and money it seems to bring the advertiser. The enormous sum spent by Palmer in advertising demonstrates the vogue he was gaining. The fellow's secret of practice was that all diseases were due to dislocated vertebræ, and so ignorant and bold had he become that he was especially curing all drunkenness by manipulations of the spine and reducing its luxations. Myopia of 13 dioptries was cured in the

same way. And yet he denounced osteopathy! By astute perseverance and great self-sacrificing labor, Dr. Andrews was able to secure facts that even a lax medical law and a quack-loving jury could not resist, and the bogus doctor suddenly found it best to move his "school" to Chicago. Five hundred dollars is the price asked by Palmer for teaching "the science," and the allurements of certain wealth is held out to the gullible. If Chicago wishes to get information of use in compelling another move on the part of Palmer, Dr. Andrews can doubtless be of service in supplying it.

Therapeutics of Formic Acid, and of the Ant and Anthill.—Every philosophic student of the history of human progress in general, and of the practice of the art of healing in particular, must be cognizant of the fact that the craving for novelty, which is so prominent a characteristic of *homo sapiens*—and especially in the most progressive communities—has been the principal cause of our neglect of many important therapeutic agents. Some of these are resuscitated when their former fame has become so completely forgotten that a renewal of the acquaintance furnishes a new item of (antiquarian) novelty. This fact is exemplified by a recent communication to the *Lyon Médical* by M. Clement on the action of formic acid. Although formic aldehyd had of recent years obtained recognition in scientific therapeutics, the corresponding acid was ignored in that department. Yet in the seventeenth century—when animal therapeutics were much in vogue—a preparation of ants formed the principal ingredient of Hoffmann's "Vinegar of Magnanimity," which enjoyed a European reputation as a stimulating cordial, stomachic and diuretic. M. Clement experimented on himself by taking ten drops of formic acid (in vichy water) four times a day. A sodium formate was, of course, thus formed. After 24 hours he experienced a distinct feeling of muscular excitement, with an increased capability of performing violent and fatiguing muscular exertions of all kinds. Those feelings were tested by ergographic records, which gave the most satisfactory corroboration. The sensations of muscular weakness and heaviness after severe exertion were to a great extent removed. Under the influence of the drug, the increase of arterial tension produced by severe effort was also markedly less. It is suggested that the enormous capacity for exertion, in proportion to individual bulk, which ants notably possess, may be in some way dependent on this fact. Their unparalleled energy did not escape the observation of the all-knowing Jewish monarch: "Go to the ant, thou sluggard, consider her ways, and be wise." Full evidence of the popularity of ants as an item of British *Materia Medica* is to be found in *The New London Dispensatory*, which received the *imprimatur* in 1676. One section of this quaint old volume is worth reading in this connection: "*Formica, Murmos, Μύρμηξ*. The Pismire, or Ant. It is a small, but a wise Creature, gathering its food in Summer in the full Moons, and resting in the new Moons. They are like a Commonwealth, and gather Corn, which they dry, and bite at both ends that they may not grow; they wear away Stones of their assiduity, and make beaten Roadways;

they help one another in drawing their burthens, dam out water, and bury their dead. The greater lead the way, and the lesser drag the corn; and when dirty, they cleanse themselves before they enter into their habitations. They teach their young to labour, but expel the idle, and when they carry their grain, it's said to be a sign of foul weather. They cast up the Earth over the mouths of their Caves (that the water may not enter in), wherein they have cells; in the one they live, in another they breed and bury, and in the third they keep their Corn. They generate in Winter, bring forth Eggs, which in Spring are Ants; when old, they grow winged, and then suddenly after die. 1. *The Ants* are hot and dry, excite Lust, and by their sharp scent, wonderfully refresh the spirits; the greater and winged, with a little salt, cure the *Psora*, or Scab, and Leprosie. 2. *Their Eggs* help thickness of hearing and deafness; being rub'd on the skin, make it smooth; and taken inwardly, expel wind; their Eggs with Bats' blood is a depilatory, used three or four times a day. 3. *The Acervus*, or Ant-hill, strengthens the Nerves, is Anodyne, and helps Gouts, Palsies, Convulsions, and Suffocation of the Wombs being applied. 4. *The Oyl of winged Ants, by infusion for 40 days*, provokes Lust, and helps the Gout and Palsie. 5. *Liquor Formicarum. Take them cleansed, put them into a narrow-mouth'd Glass, stop it, set it in brown bread in an Oven, and take it out therewith, which filter and keep for use.* Inwardly it causeth magnanimity, and cures the stone; outwardly, it helps suffusion of the Eyes, cures the Itch, and dissipates Corns and Warts."

The Hygiene of Kissing.—Any one reading the article on the "Hygiene of Kissing," by Féré,¹ must be surprised at the large number of essays on kissing that have been written by scientific men, quotations from which are scattered through Féré's paper. According to Féré kissing is a manifestation of sentiment, and also a means of evoking and exalting it. Among certain savage tribes, such as those of New Zealand and Lapland, the act of kissing is unknown, its place being taken by the rubbing of noses. The danger of kissing with respect to the transmitting of contagious and infectious diseases is now well known, and the author refers to the osculatory ordinance introduced into the legislature of Virginia by a Mr. Ware. Aside from the danger of contagion certain traumatic lesions may also be produced by the act of kissing; and in some neuropathic natures the kiss may constitute a harmful nervous shock. Féré cites a case in which an enforced kiss produced epilepsy; and another in which kissing caused a sensation of intense anxiety and inhibited the sexual act.

More about Pneumonia.—Chicago's Bulletin of the Health Department for the week ended December 26, 1903, says: "The total 139 deaths from pneumonia are the highest for any December week on record. They form 27% of the total mortality from all causes, while 49 deaths from tuberculosis are less than one-tenth the total deaths of the week. Since the forecast in the Bulletin of October 24—that there would be, between November 1, 1903, and May 31, 1904, 'upward of 2,100 deaths from pneumonia and hardly more than 1,300 from tuberculosis' in this city—there have already been 740 deaths from pneumonia and 338 from tuberculosis—and the worst 4 months of the pneumonia season are yet to come."

BOOK REVIEWS

Principles and Practice of Surgery.—By GEORGE TULLY VAUGHAN. Published by J. B. Lippincott Company, Philadelphia and London.

This is a volume of more than 500 pages, in which the author presents and discusses the various subjects which are ordinarily included in the textbooks on surgery. All the specialties which were formerly classified as belonging to surgery have been omitted by the author and he has confined himself exclusively to work in the purely surgical field. A commendable feature of the work is in the number and appropriateness of the illustrations. A considerable portion of the work is devoted to operative procedures and more than the usual space is devoted to fractures and dislocations. The subject of venereal disease has received rather limited attention, while tumors have been somewhat more amply discussed. The work is not intended as an exhaustive treatise in surgery, but rather as an endeavor to present in concise form the subject which will come more properly before the student and busy practitioner. The work is well written and the wide experience of the author as a clinician has enabled him to succeed effectually in presenting the work within the scope mentioned.

Textbook of Operative Surgery.—By THEODORE KOCHER. Fourth Edition, translated by HAROLD J. STILES. Published by Adam and Charles Black, London; The Macmillan Company, 66 Fifth avenue, New York.

A work from the pen of this wellknown surgeon with international fame cannot but attract the attention of the profession in general. The remarkable and varied experience of Kocher, of Berlin, cannot but be instructive to all surgeons, and especially the parts of his work devoted to the subject of goiter, in which he recounts more than 2,000 operations; and that devoted to hernia, in which he explains his operation, which has been widely employed, together with that devoted to operative treatment of the tongue for malignant diseases. All of these are embodied in the work under consideration. The illustrations are especially good and he devotes considerable space to the subject of local anesthesia. Much of the work is devoted to operative procedures, such as would be performed in the ordinary surgical laboratory, and on this account it is especially adapted to the use of students. The work should be in every surgeon's library.

Anatomy.—By HENRY A. HALE; edited by V. C. PEDERSON. Published by Lea Brothers & Co., Philadelphia and New York.

This work is a manual of about 375 pages, which presents the essential and important features of anatomy in a manner suited for ready reference by the student and practitioner. It consists of numerous illustrations, and each major division of the book is followed by a series of questions, which makes it especially valuable for any one desiring to briefly review the subject of anatomy. The work is well written, and will prove of value, especially for those for whom it is intended.

Johns Hopkins Hospital Reports. Volume xi. Baltimore: The Johns Hopkins Press. 1903.

This volume of the Johns Hopkins Hospital reports contains 3 articles. C. P. Emerson contributes an exhaustive paper on "Pneumothorax: A Historical, Clinical, and Experimental Study," which fills 450 pages of the volume. This article will surely be a classic reference on the subject, as mention is made of 358 contributions to the literature, and instead of simply mentioning the author's name and the place his paper appeared, an abstract of each is given, this feature occupying 197 pages of the text. Notes on some 50 cases and numerous experiments on dogs complete the article. "Clinical Observations on Blood-pressure," by H. W. Cook and J. B. Briggs, form the second article in the report. The third paper is by Martin B. Tinker on "The Value of Tuberculin in Surgical Diagnosis." The paper is based on a study of the results of injections in 400 cases and is of very great practical value to the physician as well as to the surgeon.

¹ *Rev. de Med.*, June 10, 1903, No. 6.

A Manual on the Practice of Medicine.—By A. A. STEVENS. Sixth edition, revised and enlarged. Published by W. B. Saunders & Co., Philadelphia, New York, and London.

This volume of somewhat over 500 pages, needs no comment from the reviewer, save to call attention to the fact that a new edition has appeared. The sections on diseases of the digestive system, diseases of the blood, gout, diseases of the spinal cord, and hernias, have been entirely rewritten, thus bringing the work entirely up to date. The popularity which this manual has heretofore enjoyed will be augmented by the excellence of the present edition.

A Manual of Bacteriology.—By HERBERT U. WILLIAMS, M.D. Third edition. Philadelphia: P. Blakiston's Son & Co., 1903.

The latest edition of this manual is brought down to date, and forms a book of 351 pages. A short historic sketch has been inserted, and an increased number of references to literature is given. Many of the illustrations are new. An appendix contains brief notes on the pathogenic protozoa, including trypanosomes. This work remains one of the best of the shorter treatises on the subject.

Consumption a Curable and Preventable Disease.—By LAWRENCE F. FLICK, M.D. Philadelphia: David McKay, Publisher. 1903.

The sub-title of this book on pulmonary tuberculosis is "What a layman should know about it," and the author states in the preface that the recent rapid growth of knowledge regarding tuberculosis has been disquieting to those who have obtained but little. To allay unnecessary fear regarding the contagiousness of the disease and to restore a sense of propriety and responsibility toward the poor tuberculous, is the purpose of the writer. We believe that he has accomplished much toward his aim. While the style of the book is of necessity popular in character, we do not find constant misstatements of small scientific truths as are found in so many books of this class. Facts regarding the cause and spread of tuberculosis are set forth in plain words and directions for the tuberculous and those around him are tersely supplied. That the process of arrest or healing in favorable cases is of slow development is rightly emphasized. The book should have a wide circulation among the laity, and physicians will do well to so advise.

Transactions of the Congress of American Physicians and Surgeons.—Sixth Triennial Session held at Washington, D.C., May 12-14, 1903. Published by the Congress, New Haven, Conn., 1903.

This volume of 243 pages contains the papers read at the scientific sessions of the Congress which were devoted to the consideration of 2 topics: "The Pancreas and Pancreatic Diseases," and "The Medical and Surgical Aspects of the Diseases of the Gallbladder and Bile Ducts." Those authorities contributing papers on the former subject are Opie, Chittenden, Flexner, Fitz, von Mikulicz-Radecki, and Park. Papers on the latter topic are by Ewald, Musser, Brewer, Herter, Mayo, and Kehr. Discussion of these questions by members of the Congress is also included. It is almost needless to add that these papers collectively present in a concise manner the present status of our knowledge regarding the subjects in question. The Transactions also contains President Keen's masterly address on "The Duties and Responsibilities of Trustees of Public Medical Institutions."

A Surgical Handbook: Twelfth Edition.—By FRANCIS M. CAIRD and CHARLES W. CATHCART. Published by Charles Griffin & Co., London, and W. T. Keener & Co., of Chicago.

This little work of something more than 300 pages is devoted to a discussion of the principal surgical ailments which come under observation in the hospital and clinic. It of necessity discusses these subjects very briefly but clearly and to the point. A valuable feature consists in presenting numerous illustrations and short descriptions of apparatus used in surgical clinic and in connection with surgical cases. These are most excellent and the little work is eminently practical and convenient for ready reference.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Blood-Pressure in Surgery: An Experimental and Clinical Research. The Cartwright Prize Essay for 1903.—By GEORGE W. CRILE, A.M., M.D., Professor of General Surgery, Western Reserve Medical College; Visiting Surgeon to St. Alexis Hospital; Associate Surgeon to Lakeside Hospital, Cleveland. J. B. Lippincott Company, Philadelphia and London, 1903.

The Treatment of Fractures: With Notes Upon a Few Common Dislocations.—By CHAS. L. SCUDDER, M.D., Surgeon to the Massachusetts General Hospital. Fourth edition, thoroughly revised, enlarged and reset. Octavo volume of 534 pages, with nearly 700 original illustrations. Philadelphia, New York, London. W. B. Saunders & Co., 1903. Polished buckram, \$5.00 net; sheep or half morocco, \$6.00 net.

Organic and Physiologic Chemistry: A Manual for Students and Practitioners.—By ALEXIUS MCGLANNAN, M.D., Associate Professor of Physiologic Chemistry, Instructor in Clinical Laboratory, College of Physicians and Surgeons, Baltimore, Md. Series edited by V. C. PEDERSEN, A.M., M.D., Instructor in Surgery and Anesthetist and Instructor in Anesthesia at the New York Polyclinic Medical School and Hospital; Deputy Genitourinary Surgeon to the Out-Patient Department of the New York Hospital; Physician-in-Charge St. Chrysostom's Dispensary; Anesthetist to the Roosevelt Hospital (First Surgical Division). Illustrated with 9 engravings. Lea Brothers & Co., Philadelphia and New York.

A Compend of Pathology: General and Surgical. A Students' Manual in one volume.—By ALFRED EDWARD THAYER, M.D., Professor of Pathology, University of Texas. Second edition, containing 131 illustrations. P. Blakiston's Son & Co., Philadelphia, 1903.

Progressive Medicine, Vol. IV, December, 1903: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences.—Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Octavo, handsomely bound in cloth, 434 pp., 46 illustrations. Lea Brothers & Co., Publishers, Philadelphia and New York.

First Report of the Trypanosomiasis Expedition to Senegambia (1902), of the Liverpool School of Tropical Medicine and Medical Parasitology.—By J. EVERETT DUTTON, M.B., B.Ch., Vict.; WALTER MYERS, Fellow the University, Liverpool; and JOHN L. TODD, B.A., M.D.; C.M., MCGILL. With notes by H. E. ANNETT, M.D., D.P.H., and an appendix by F. V. THEOBALD, M.A. Published for the University Press of Liverpool by Longmans, Green & Co., London, New York and Bombay, 1903.

Fourth Annual Report of the Work of the Cancer Laboratory of the New York State Board of Health. Conducted at the Gratwick Research Laboratory, University of Buffalo. For the year 1902-1903.

Description of Brain and Spinal Cord in Hereditary Ataxia.—By LEWELLYS F. BARKER, M.D., Professor and Head of the Department of Anatomy, University of Chicago. The decennial publications of the University of Chicago, first series, Vol. x, 38 pp. with three heliotype plates and 40 figures. Net, \$2.00; postpaid, \$2.08. The University of Chicago Press, Chicago, Illinois.

Philadelphia Hospital Reports: Vol. v, 1902.—Edited by HERMAN B. ALLYN, M.D. Printed by Maurice H. Power, Philadelphia, 1903.

The Practical Care of the Baby.—By THERON WENDELL KILMER, M.D., Associate Professor of Diseases of Children in the New York School of Clinical Medicine; Assistant Physician to the Out-Patient Department of the Babies' Hospital, New York; Attending Physician to the Children's Department of the West Side German Dispensary, New York. With 68 illustrations. Extra cloth, \$1.00 net, delivered. Philadelphia: F. A. Davis Company, Publishers.

The Treatment of Neurasthenia.—By A. PROUST, M.D., Professor of the Faculty of Medicine, Paris; Inspector-General of the Sanitary Service; Member of the Academy of Medicine, etc.; and GILBERT BALLEZ, M.D., Fellow of the Faculty of Medicine, Paris. Translated by PETER CAMPBELL SMITH, L.R.C.P., L.R.C.S., Edin., L.F.P.S., Glasgow. New York: Edward R. Pelton, 1903.

Anatomy Applied to Medicine and Surgery.—By D. E. MUNDALL, B.A., M.D., Professor of Applied Anatomy, Faculty of Medicine, Queen's University; Ex-Examiner Practice of Medicine, Ontario Medical Council; Surgeon to Kingston General Hospital, Kingston. Printed at the British Whig, 1903.

Quiz Compend: Diseases of the Ear, Nose and Throat.—By JOHN JOHNSON KYLE, B.S., M.D., Lecturer on Otolaryngology and Laryngology, and Assistant to the Chair of Surgical Pathology in the Medical College of Indiana; Oculist and Aurist to St. Vincent Hospital and City Dispensary; Aurist and Laryngologist to City Hospital, Indianapolis, etc. With 85 illustrations. P. Blakiston's Son & Co., Philadelphia, 1903. Price, 80 cents net.

A Non-surgical Treatise on Diseases of the Prostate Gland and Adnexa.—By GEORGE WHITFIELD OVERALL, A.B., M.D., Formerly Professor of Physiology in the Memphis Hospital Medical College. Rowe Publishing Company, Chicago, Ill.

Portfolio of Dermochromes.—By PROFESSOR JACOB. English adaptation of text by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, London. Rebman Company, New York, 1903.

Mt. Sinai Hospital Reports: Vol. III, for 1901 and 1902.—Edited for the Medical Board by N. E. BRILL, A.M., M.D., 1903.

The Principles of Open-Air Treatment of Phthisis and of Sanatorium Construction.—By ARTHUR RANSOME, M.D., M.A., (CANTAB.), F.R.C.P., F.R.S., Honorary Fellow of Gonville and Caius College, Cambridge; Consulting Physician to the Manchester Hospital for Consumption and Diseases of the Chest and Throat; Late Examiner in Public Health at Cambridge and Victoria Universities. Smith, Elder & Co., London, 1903.

Special Report on Diseases of the Horse.—By DRS. PEARSON, MICHENER, LAW, HARBAUGH, TRUMBOWER, LIANTORD, HOLCOMBE, HUIDEKOPPE, STILES and ADAMS. Revised edition. Government Printing Office, Washington, D. C., 1903.

AMERICAN NEWS AND NOTES.

GENERAL.

Requests to Charity.—CHICAGO: According to the will of the late Leopold Mayer, charity bequests are: Jewish Training School of Chicago, \$1,000; Chicago Home for Jewish Orphans, \$2,000; the Uhlich's Orphan Asylum, \$500; German Catholic Orphan Asylum, \$500; the Jewish Orphan Asylum, Cleveland, \$500; the German Altenheim, \$500; Harmonia Lodge, Odd Fellows, \$500; Michael Reese Hospital, \$500; Home for Aged Jews of Chicago, \$500; Hebrew Union College of Cincinnati, \$500. PHILADELPHIA: By the will of Cordelia A. Brown, \$5,000 is given to the Methodist Episcopal Hospital to endow a free bed in the memory of William Brown, her husband.

Deathrate in Cities of 200,000 and Over.—From the census of 1900, it appears that the deathrate in the cities named below was as follows: Boston, 20.1; Buffalo, 14.8; Detroit, 17.1; Jersey City, 20.7; Newark, N. J., 19.8; Washington, D. C., 22.8; Baltimore, Md., 21; Chicago, Ill., 16.2; Cincinnati, 19.1; Cleveland, 17.1; Louisville, 20; Milwaukee, 15.9; Minneapolis, 10.8; New Orleans, 28.9; Philadelphia, 21.2; Pittsburgh, 20; St. Louis, 17.9; San Francisco, 20.5. An encouraging feature is that in a number of these cities the deathrate has been materially reduced since the above date. For example, in New York, where the deathrate for 1903 is estimated at but 18.15 per 1,000, and in Chicago it is materially lower.

Miscellaneous.—NEW JERSEY: Dr. Ellen L. Lowell, of New York, has been appointed chief bacteriologist at the Graves Pathological Laboratory of the Orange (N. J.) Memorial Hospital. She will have entire charge. She is a graduate of Leland Stanford University, and received her degree of M.D. from Johns Hopkins University. COPENHAGEN: A meeting was held on December 10 at the Phototherapeutic Institute, Copenhagen, in celebration of Professor Finsen's success in obtaining the Nobel prize for medicine. It was announced that Professor Finsen had decided to give 50,000 kroner from the amount awarded to him to the institute, and that 2 members of the governing body would each present it with a like sum.

Favors the Metric System.—The following bill has been introduced into the House of Representatives and referred to the Committee on Coinage, Weights, and Measures. Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That on and after the first day of January, 1905, all the departments of the Government of the United States, in the transaction of all business requiring the use of weight and measure, except in completing the survey of public lands, shall employ and use only the weights and measures of the metric system; and on and after the first day of January, 1906, the weights and measures of the metric system shall be the legal standard weights and measures of and in the United States.

Salicylic Acid Harmful.—The food test at the Department of Agriculture, which has been going on for several months past, to test the effect of salicylic acid on human health, has brought out some queer results. The general fact is established that salicylic acid seriously injures health. One man, however, has reason to rejoice in the salicylic acid treatment. It has cured his rheumatism. The experiments have been abandoned to save the subjects, but will be resumed when the men have recovered somewhat from the effects of the past 2 months' diet on prepared foods into which salicylic acid enters as a preservative. Dr. Wylie says that he expected this result. This experiment has turned out just as did that with foods preserved with borax. That made the men all sick.

Tuberculosis in Hens.—Now that his experiments with diseased fowls in California have demonstrated the fact that tuberculosis is one of the most widely prevalent diseases in the poultry ranches of the State, Dr. Archibald R. Ward, veterinarian of the University of California Agricultural Department, is pursuing investigations to discover whether there is any relationship between this and bovine or human tuberculosis. Furthermore, the consideration of the possible significance of fowl tuberculosis has awakened the desire to know whether or not the deadly organisms are present in the egg. Both these points are vitally important, and the Animal Industries Department, in conjunction with the recently established Poultry Experiment Station, will make a careful study of the cases that are brought to their attention.

Important Gifts during 1903.—One hundred million dollars has been mentioned as a low estimate of the aggregate gifts made to religion, education, and charity during the year 1903. Some of the important gifts to medical science and to charitable purposes are as follows: John D. Rockefeller, to Rush Medical Institute of Chicago, \$7,000,000; Andrew Carnegie, for the endowment of a fund for the relief of injured men of the steel works at Homestead, \$4,000,000; the Phipps Consumptive Hospital Fund of Philadelphia, \$1,250,000; the Jeanes gift for a Home for Aged Quakers, in Germantown, Philadelphia, \$1,000,000; the Maxwell additions to Long Island Hospital, \$600,000; Mrs. Appleby's gift of \$2,500,000 to be invested for

the benefit of the poor of St. Paul, Minn. It is an interesting fact, says the *Public Ledger* of Philadelphia, that, while many of these gifts are to causes outside all churches, the funds for them are given in fully 75% of the total by persons inside of the churches. The *Church Economist* estimates the cost of maintenance of all churches in America to be \$60,000,000 a year. Not only do Christian people give almost all of this vast sum, but they also give fully \$75,000,000 of the \$100,000,000 going to causes outside of the churches each year.

EASTERN STATES.

Large Fund to Erect and Maintain a Hospital.—The will of the late Peter B. Brigham of Boston, who left \$5,000,000 toward founding a hospital to bear his name, is sustained by a decision handed down by Justice Colt in the United States Circuit Court. The heirs at law contested the bequest.

Epileptic Children.—The report of the trustees of the Massachusetts Hospital for Epileptics at Palmer, states that at various times during the past 2 years it has been brought to the attention of members of the board that no adequate provision is made for the large number of epileptic children now in the State. The matter has been placed in the hands of a committee of the trustees, in order that it may be carefully considered from all sides. It seems probable, however, that it will be deemed advisable that this institution should make provision for epileptic children, and in this case, steps will be taken in this direction in the near future. This is a subject of the most serious importance, and special attention is now directed to it.

NEW YORK.

To Prevent the Spread of Tuberculosis.—Resolutions have been adopted by the Board of Health of New York City that no member of the police or fire departments is to remain on duty when suffering from tuberculosis in its infectious stage. This action was the outcome of an investigation which disclosed the fact that 17 members of the police are afflicted with the disease.

New York Academy of Medicine.—A stated meeting was held in Hosack Hall, Thursday evening, January 7, 1904. William P. Spratling, superintendent of Craig Colony for Epileptics, presented a paper on "Guides to the Prognosis in Epilepsy, with Remarks on the Curability of the Disease." The paper was discussed by Drs. M. Allen Starr, Charles L. Dana, L. Pierce Clark, Pearce Bailey, Frederick Peterson, and others.

Lowest Deathrate Since 1800.—Health Commissioner Lederle recently sent to the then Mayor Low a preliminary report of the work done by his department during the year. Despite the normal increase in the population, Dr. Lederle reports that up to December 21 last year there were 470 fewer deaths than in the corresponding period of the previous year. With the exception of diphtheria, there has been a decrease in the number of deaths caused by strictly contagious diseases. There were 9,460 more births this year than last. The deathrate was 18.11 in the 1,000, as compared with 18.77 in 1902, and 20 in 1901. In the old city of New York the deathrate was 19.10, the lowest since 1800. It was 19.49 in 1902, which was the next lowest. Dr. Lederle says: "Another evidence of increasing healthfulness of the city is found in the fact that the only increase in the number of deaths is found in those of persons 65 years and over, which would indicate that preventive health measures have a marked effect in preserving life during the period in which the living are most useful members of society."

PHILADELPHIA, PENNSYLVANIA, ETC.

Licensed to Practise Medicine.—The State Board of Medical Examiners for Pennsylvania has made public the list of successful applicants for license to practise medicine in this State. Of 103 applicants who took the examinations but 57 passed, the failures reaching 42.20%. This large percentage of failures is due to the severe examinations, which were a great deal more difficult this year than ever before.

Butler Epidemic under Control.—According to the latest reports, it is indicated that the hospital improvised by the relief committee in caring for the stricken victims of Butler epidemic, will be dispensed with about the middle of January. Some of the nurses and physicians who have been sent from Philadelphia and other places are returning, all of which indicates that the epidemic, though still serious, is at least under control.

Improved Health Records in Camden.—The Camden Board of Health instructed its solicitor recently to meet the Ordinance Committee for the purpose of framing an ordinance governing the use of soft coal within the city limits. It was decided to enforce a recent resolution requiring physicians to report cases of chickenpox to the Board as a contagious disease. The report of Health Officer Leavitt showed the city entirely free of smallpox, the last 2 patients having left the isolation hospital. Other cases of contagious diseases were reported as follows: Diphtheria, 18; membranous croup, 1; scarlet fever, 33; and tuberculosis, 4. There has not been a case of typhoid fever since October 22. The health officer's report stated that the city is in a healthier condition than has been known for many months.

Pneumonia and other Diseases in Philadelphia.—For the week ended January 2, there was no abatement of the smallpox and typhoid epidemics in the city, there being reported 74 new cases of the former and 150 new cases of the latter; and the deathrate for the week from all causes numbered 602 as compared to 554 for the previous week and 532 for the corresponding week last year. Pneumonia prevails to a great extent and there were 95 deaths from this disease during the week, comprising almost one-sixth of the total number of deaths from all causes.

Meeting of Scientific Societies at University of Pennsylvania.—Recently 5 affiliated scientific societies have held simultaneous meetings at the University of Pennsylvania. A large number of scientists, many of them of national reputation were present and engaged in scientific discussion. The affiliated societies are the Society of American Bacteriology, the Society for Plant Morphology and Physiology, the American Society of Zoologists, the Association of American Anatomists, and the American Physiological Society. A number of important papers were presented and discussed.

College of Physicians, Philadelphia.—The section on general medicine, announces the following program for its next meeting, to be held in the upper hall of the college, Monday evening, January 11, 1904, at 8.15 o'clock.

SYMPOSIUM ON THE EARLY MANIFESTATIONS OF CIRRHOSIS OF THE LIVER.

1. Pathologic Anatomy, Dr. W. W. Ford, of Baltimore.
2. Clinical Chemistry, Dr. David L. Edsall, of Philadelphia.
3. Clinical Manifestations, Dr. Charles G. Stockton, of Buffalo.

The papers will be discussed by Doctors Tyson, Musser, and Hare.

Foreign Immigrants Arriving in Philadelphia.—According to the report of Commissioner of Immigration, there arrived in the port of Philadelphia during 1903, 53,092 aliens, an increase of 34,165 over the previous year, and 4½ times the number which arrived during 1901. The largest number of immigrants were from the following countries in the order named: Russian Empire, Austria-Hungary, England, Ireland, Germany and Italy. More than 5% were illiterate and 71 were deported on account of being afflicted with contagious or loathsome diseases. During the year 1,120 aliens were relieved in hospitals.

SOUTHERN STATES.

Mortality in Baltimore.—During the week which ended at noon January 2, there were 194 deaths in Baltimore, as against 214 for the corresponding week last year, 183 in 1902 and 186 in 1901. The annual deathrate per 1,000 was: Whole population, 18.26; white, 17.18; colored, 24.44.

Smallpox Epidemic Reported in Texas.—Information from Sour Lake, Texas, under date of December 31, says: The outbreak of smallpox here has become a very serious matter. One physician states that there are fully 200 cases and there have been 5 deaths in the past few days. The State health authorities were asked to take the matter in charge, but so far nothing has been done in that direction. There is no municipal government, and matters may grow much worse.

Alcohol and Insanity.—The *Baltimore Herald* says: The attention of those who take a little something for their appetite and of those who have not yet reached the stage in which the hideous things of nature become visible is respectfully called to the report of Dr. J. Percy Wade, superintendent of the Maryland Hospital for the Insane, who declares that there is an alarming increase in the number of men who are afflicted with insanity caused by the use of alcohol. Dr. Wade also says that the number of alcoholic patients is constantly multiplying. Most people are inclined to look upon the delirium tremens as something amusing, but the aspect of the case pointed out has nothing comical about it. Its extreme gravity should cause people to stop and think. The alcohol habit is growing. Possibly much of it is due to the nervous tension of the times, but whatever the cause, the effect should be remembered when confronted by the foolish persuasion that the high pressure of an unnatural life can be relieved by over-stimulation.

WESTERN STATES.

No Leprosy in Nebraska.—The scare occasioned in Lincoln by the report that 25 cases of leprosy had been discovered in the Russian colony, has been dispelled by the report of the Health Commissioner, who made a thorough investigation of the suspected cases. Instead of being leprosy, the disease is a harmless skin affection.

Does Radium Exist in Colorado?—According to reports from Denver, not long ago it was alleged that a certain spot in Utah was more or less stocked with radium, the new and wonderful element. Colorado now makes the same claim. Professor W. D. Engle, of the University of Denver, and Justin H. Haynes, a chemist, say they have discovered that radium exists in the mines of Colorado, and declare that it can be procured here in larger quantities than in any other part of the world.

FOREIGN NEWS AND NOTES

GENERAL.

Enteric Fever in London Watercress.—In June, July and August, a period of the year when enteric fever cases are usually below the average, the disease broke out with such severity in London, as to cause Dr. King Warry, the medical officer of health, to make a special investigation into the causes. Localization of the disease led Dr. Warry to seek for a special cause for the outbreaks, and while examining the known media, i. e., water, milk, shellfish, ice cream, fried fish, and sanitary defects—he was struck by the large number of watercress eaters among those affected. Bacteriologic examination of the watercress submitted for sale in the locality showed many specimens teeming with typhoid bacilli. Much of the watercress had grown in the almost undiluted sewage from portions of the city.

Leprosy in Colombia.—M. Beaupre, United States Minister to Colombia has transmitted to the State Department a copy of a law enacted by the Colombian Congress providing for the isolation of lepers in each department of the republic. "One of the gravest questions confronting Colombia in these days," says Mr. Beaupre, "is the terrible one of leprosy. This awful disease has invaded the country to an alarming extent, and extraordinary measures have been found necessary to check its spread." The act provides that leper asylums are to be established in each department of the republic, the central idea being isolation. For the Department of Antioquia there already is conducted a leper asylum, at an expense of more than 3,000,000 pesos.

Brain Work Does not Kill.—In the lecture on longevity delivered recently before the Royal College of Physicians, Sir Hermann Weber, himself an octogenarian, gave official support to the doctrine that brain work does not kill, but rather the reverse says the *London Chronicle*. A few of his instances are Sophocles, Plato, Galen, Cicero, Moltke, Bismarck, Mommson, and Gladstone, to whom we might add Hobbes, Carlyle, and with Kelvin still living. The facts are that brain work increases the supply of blood to the nerve cells, and promotes their nutrition and health. Mosso, an Italian, laid a man on a delicately balanced table, and showed that the head end sank whenever the subject did a mental sum or any other brain work. The increased weight of his head was due to the life-giving blood. The truth is that brain work, as such, never killed anybody.

CONTINENTAL EUROPE.

Röntgen Ray Congress.—A special Röntgen Congress and Exhibition is to be held at Berlin during the spring to celebrate the tenth anniversary of the discovery of the Röntgen rays. Professor Röntgen is expected to be present at the Congress. Further information can be obtained from Dr. Immelmann, Lützowstr, 72, Berlin, W., Germany.

OBITUARIES.

Frances E. White, one of the most widely known women physicians in the United States, recently at Jamaica Plain, Mass. She was for many years professor of physiology and hygiene at the Woman's Medical College of Pennsylvania, and was graduated from that college in 1872. She resigned her chair last May on account of ill health. At that time she was elected an emeritus professor. Dr. White was one of the first women to lecture before the Franklin Institute, and was a delegate to the International Medical Congress held in Berlin, being the first woman to act in that capacity. Shortly after her graduation she was made demonstrator in anatomy and an instructor in physiology. She was one of the founders of the Alumni Society of the college.

Hamilton A. West, at his home in Galveston, Tex., December 30, after a brief illness. Dr. West was secretary of the Board of Health in Galveston at the time of the great flood. For many years also he was secretary of the State Medical Society of Texas. Dr. West was born in Russell's Cave, Ky., on March 31, 1859. He was graduated with the honors in Louisville, Ky., where he took his degree of M.D. He became a professor in the University of Texas, and it was largely due to his efforts that the medical department of that university was founded. He made a special study of typhoid, yellow, and dengue fevers. He also wrote on the subject, pointing out the distinctions in the diagnosis of the two latter fevers which have often been confounded.

Byron Hiram Daggett, at his home in Buffalo, N. Y., December 30; a graduate of the medical department of the University of Buffalo in 1887. He was known in the surgical world as the inventor of a surgical table which is in general use among surgeons throughout the country. He was a former health physician and police surgeon of Buffalo, a member of all the Buffalo medical societies, an editor of the *Buffalo Medical and Surgical Journal*, a writer for the *New York Medical*

Journal and the New York Medical Record, and a member of the staffs of the Emergency, Sisters' and Riverside Hospitals of Buffalo.

J. H. Vastine, at his home in Catawissa, Pa., of Bright's disease, January 3, aged 68; a graduate of Jefferson Medical College, and an army surgeon during the Civil war, in which he served with the One Hundred and Thirtieth Pennsylvania Volunteers. He was one of the oldest practising physicians in his section of the State, and at the time of his death was president of the First National Bank of Catawissa and a director of the First National Bank of Bloomsburg.

Anton Eldenbenz, at St. Luke's Hospital, N. Y., of pneumonia, January 1, aged 88. He was born in Germany and graduated in medicine from the University of Giessen, Germany, in 1846, but practised in New York City for more than 50 years. He was surgeon to the Eleventh New York Regiment during the Civil war, and for many years was visiting surgeon to St. Luke's Hospital.

T. G. Birchett, at his home in Vicksburg, Miss., January 2, aged 68; a graduate of the University of Pennsylvania in 1856. He was twice mayor of Vicksburg, served several terms in the city council and the Mississippi Legislature, and was for years superintendent of the Mississippi State Hospital at Vicksburg.

Harry C. Hume, at his home in New Harmony, Ind., December 17, of consumption, aged 30; a graduate of the Kentucky School of Medicine, Louisville, in 1892; member of the American Medical Association and Greene County Medical Society.

William S. B. Henry, at his home in Falls Church, Va., December 12, aged 76; a graduate of Jefferson Medical College; surgeon to the Fortieth Virginia Infantry, C. S. A., and formerly physician to the Omaha and Winnebago Agency in Nebraska.

E. M. Hardcastle, at his home in Easton, Md., December 27, aged 85; a graduate of Jefferson Medical College in 1884. For 55 years he practised his profession in Trappe, Talbot county, Md., but for the past 7 years had lived in Easton.

Gustavus Adolphus Haefner, formerly of Baltimore, January 3, at his home in Hurloch, Md., aged 59; a graduate of the University of Maryland in 1866. He served as medical officer in the Federal army during the Civil war.

Thomas B. Welch, at his home in Vineland, N. J., December 29, where he had resided for many years. He was an active prohibitionist and the originator of prepared grape juice for communion purposes.

Horace Clifton Taylor, at his home in Brockton, N. Y., December 27, aged 90; a graduate of the Eclectic Medical Institute, Cincinnati, in 1849. He was known as an author of works on the care of the indigent.

Samuel B. Howell, at Atlantic City, N. J., December 12. He was one time secretary of the College of Physicians, Philadelphia, and one of the founders of the Medico-Chirurgical College, Philadelphia.

Frank S. Jackson, at his home in Dunkirk, N. Y., January 1, aged 52; a graduate of the University of New York, from which place he went to Dunkirk, where he practised for more than 30 years.

William H. A. Young was killed by the accidental discharge of a rifle at his home in Springfield, Mass., December 26; a graduate of the Eclectic Medical College of the City of New York in 1912.

Leopoldo Bertini, in Rome, Italy, December 10, 1903. He was chief surgeon to the hospital of San Giacomo for many years, and noted for the introduction of many surgical appliances.

Francis A. Kitchen, at his home in Toledo, December 18, of pneumonia, aged 83; a graduate of the University of Pennsylvania in 1856, and an army surgeon during the Civil war.

J. Reynolds Tillinghast, Jr., of Saranac Lake, N. Y., at Colorado Springs, December 13, of consumption; a graduate of the College of Physicians and Surgeons, N. Y., in 1895.

J. W. Hamilton committed suicide in his room in San Francisco, December 14, aged 66; a graduate of Bennett College of Eclectic Medicine and Surgery, Chicago, 1870.

John M. Otto, in the New York Hospital, as the result of fracture of the skull from an accidental fall, December 20; a graduate of the University of New York in 1899.

Z. T. Scott, at his home in Hazlehurst, Miss., December 23, aged 75. He was a prominent citizen of the locality and had practised in that vicinity for many years.

Michael O'Malley, on December 26, at St. Agnes Hospital, Philadelphia, of pneumonia, aged 78. He was a retired army surgeon and veteran of the Civil war.

Charles A. Moran, at St. Joseph Infirmary, in Atlanta, Ga., December 20, aged 45; a graduate of the Southern Medical College, Atlanta, in 1885.

Henry J. Bowers, at his home in Myerstown, Pa., December 31, of diabetes, aged 62; a graduate of Jefferson Medical College in 1862.

Elias H. Frantz, at his home in Reading, December 30, aged 56; a graduate of Jefferson Medical College in 1873.

Silas J. Damon, at his home in Bridgeport, Conn., January 1, aged 58. He was a wellknown eclectic physician.

Robert Boocock, at his home in Brooklyn, December 28. He was a wellknown Homeopathic physician.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

TUBISM—LAVAGE HABIT.¹

BY

C. D. SPIVAK, M.D.,
of Denver, Col.

During the first years of my professional life—and they did not begin until many years after the Civil war—patients came to me who never heard of the stomach tube, and who were "scared to death" when I explained to them the harmless and painless procedure of swallowing a small piece of rubber tubing. I used to show them only a few inches of the tube, hiding its full length from their gaze, never daring to expose the funnel end. Experience taught me that many patients believe that everything in sight is to go into the stomach—tube, funnel, and pitcher. Sometimes it took considerable persuasive eloquence, combined with a popular lecture on anatomy, supplemented by a glowing description of the untold benefits derived from its use to induce a patient to undergo this trifling operation. And then, oh, what hard times followed when the tube touched the incisors, the patient commenced to struggle for breath; when it touched the palate there was cyanosis, and when it reached the pharynx, respiration was completely suspended, and the tube, together with the operator, were roughly handled by the dazed and crazed patient. What a coughing, hawking, spitting, groaning, sneezing, struggling, and occasionally swearing there were!

Those horrid days are gone, and it is all different now. Even he from the backwoods has heard of the tube, has seen it used by his dyspeptic neighbor, nay, the majority of those who come to me now have already had "a taste of the hose." The suggestion of using the tube, which by an old habit, I always make in a rather subdued and trembling tone, no longer surprises anybody. The number of those who need coaxing is diminishing rapidly, and will soon entirely disappear. Most of the symptom-complex which accompanied the exhibition of the tube are entirely absent, and those that manifest themselves are of a mild type. The spread of knowledge has lightened the labor of the gastroenterologist, and another proof has been added to the assertion that the mind exerts a powerful influence over the body.

But the beneficent effect of diffused knowledge is not an unmixed blessing. Patients now-a-days go to the other extreme; their timidity has turned into reckless daring; they begin to use the tube without even consulting a physician, and having secured, or imagined they secured some relief from its use, they go on using it frequently, and injudiciously—they become slaves to this habit—tubomaniacs. The number of such patients is as yet insignificant. The greatest number of victims, however, is found among those who have at one time received treatment at the hands of physicians, and who were encouraged or at least permitted to use the tube themselves. They use the tube morning, noon, and evening; they use it under the slightest provocation—for a little heartburn, slight heaviness at the pit of the stomach, headache, backache, dysmenorrhea, impotence, and what not. There are unfortunates who carry in their traveling grips a stomach tube alongside of their fountain syringe, and then treat both ends of the digestive tract by hydraulic pressure. Now and then such *waxy-tube-outcasts* come to me who, instead of being coaxed into swallowing the stomach tube, seek relief from complaints induced by its abuse, and who have to undergo a systematic course of weaning from "tubism."

Now cases of gastric disturbances that need lavage are very limited, not more than 20%—rather less than more. It is seldom necessary to wash a stomach daily. The majority of cases in which lavage is indicated, 2 or 3 times a week is sufficient for all purposes. I use the stomach tube in all gastropaths for pur-

¹Read before the Medical Society of the City and County of Denver, November 3, 1903, as one of six "five minute talks" given by members of the Society, following the alphabetic order of the membership roll, after the regular program of the meeting.

poses of gastric analysis, and find after considerable experience, that 80% will do well on a treatment of regulated diet, medicine, massage, physical culture, outdoor life, and hydrotherapy.

I need not tire you with a recital of a series of cases of "tubism" that came under my observation. As an illustration a case will suffice.

M. B., a physician, was referred to me by Dr. Gildea, of Colorado Springs. The patient's health began to fail in 1896-97 while an interne in a hospital in New York. She ascribed her condition to hard work, poor food, and close confinement. The chief symptoms were poor appetite, frequent eructation of gas, borborygmus, and the passage of small, soft, sour-smelling stools 2 or 3 times a day. She was treated for endometritis, which was thought to have been the cause of her ill health. In November, 1898, she commenced to cough. In 1899 tubercle bacilli were found in her sputum, when she went to Colorado. Although she gained somewhat in weight, and her pulmonary symptoms disappeared, her gastrointestinal symptoms did not improve. She had frequent evacuations from her bowels, especially after meals. In 1900 she noticed mucus in the stools. She flushed the colon daily with salt solution, but noticed no improvement. During the warm weather diarrhea set in, complete anorexia, and she lost 20 pounds in weight. In 1901 she went to California, where she remained for 6 months. In June of that year she commenced to wash her stomach daily, and continued to do so until she came under my observation March, 1902—10 months of daily lavage! She complained of pain in the lower part of the abdomen, worse toward evening and after exercise. She suffered a great deal from flatulence and occasional eructation of gas. Appetite was poor. Stools were irregular and musty. Physical examination of the abdominal viscera revealed tenderness over the ascending and descending colon. Stomach contents showed normal quantity of hydrochloric acid; gastric motility normal, digestion good. Examination of feces showed fermentation, mucus, white blood corpuscles, numerous starch granules, and vegetable cells. A diagnosis was made of chronic enterocolitis. Treatment consisted of an antidiarrhetic diet, rest in bed, intestinal antiseptics, use of lavage was interdicted. Patient got rid of her intestinal symptoms in 4 weeks. No relapse during 20 months. She weighs now 175 pounds.

From the study of my cases I make the following deductions:

1. Lavage of the stomach is used by physicians without due discrimination.
2. The stomach tube should never be allowed to be used by the patients themselves.
3. That the dictum, "Physician heal thyself!" in so far as it least as it concerns gastric troubles is not tenable.
4. That to the many acquired vicious habits must now be added that of "tubism."

NEED OF WARD IN GENERAL HOSPITALS FOR TREATMENT OF MENTAL DISORDERS.

BY

FREDERICK PETERSON, M.D.,
of New York City.

To the Editor of *American Medicine*:—I was glad to see in *American Medicine* for December 19, Dr. Rhein's article on the need of a ward in general hospitals for the treatment of mental disorders, and I hope it will lead to a general recrudescence of a scheme which has been advocated for many years. In January, 1890, a committee of the New York Neurological Society, consisting of Drs. Dana, Parsons, and myself, appointed to comment upon some pending lunacy laws, added to its report the following paragraph:

A clause should be introduced into the bill providing that nothing in the lunacy laws of the State shall be construed to interfere with the reception and treatment of acute cases of insanity in chartered general hospitals, in the same manner and under the same conditions as patients suffering from other diseases are there received and treated, provided such hospitals have suitable accommodations approved by the State Commission in Lunacy.

The *New York Medical Journal* spoke editorially in its issue of February 22, 1890, as follows in relation to this committee's report:

We cannot speak too favorably of the action of the committee of the New York Neurological Society. Their proposition to place it in the power of the 63 chartered general hospitals of this State to open special wards for the reception of the acutely insane, under the same conditions precisely as other

classes of patients are received, would lead to vast improvement in the early and efficient treatment of the nutritive disorders of the brain. It would create a number of reception wards in various parts of the city and State, where there is now absolutely no place for such purpose.

Dr. Rhein states that he knows of "no ward of this kind in the United States, England, or France." Such wards have been quite common on the continent, especially in Germany and Austria, where they are now being replaced to a great extent by the "psychiatrische klinik" of the German universities. That in the Charité in Berlin, is now a separate pavilion of the rejuvenated Charité. Ureywert's old wards for the insane in the general hospital at Vienna still exist. The Solfèrièrè in Paris is a general hospital which has had a department for the insane since time immemorial. Many similar examples could be cited abroad. In this country the city of New York has maintained a division for mental diseases in the Bellevue Hospital for 20 or 30 years, and vastly improved quarters for such patients are to be a feature of the new Bellevue Hospital about to be constructed. It is possible that the trustees may, as they have been advised to do, create similar departments in the two large city general hospitals in course of erection in Harlem and the Borough of Bronx. The insane department of the Albany General Hospital, established within a few years, has had a notable success.

THROMBOSIS OF THE LEFT FEMORAL VEIN FOLLOWING ASEPTIC LAPAROTOMY.

BY

JOHN G. SHELDON, M.D.,
of Telluride, Colo.

Thrombosis of the femoral vein following aseptic laparotomy, is a rare occurrence. One case has occurred in my practice, and I have personal knowledge of a similar case that occurred in the practice of a neighboring surgeon. The condition is one that comes without warning and without prodromes that would lead one to suspicion its occurrence. For these reasons it is of importance, and warrants careful study. So far I have been unable to satisfy myself as to the immediate or remote causes of the condition, or how we can prevent or guard against its occurrence.

The following is the report of a case that occurred in my practice over 2 years ago:

Mrs. T., aged 38, was operated on in the following manner: A median incision was made. The left ovary was found to be cystic and as large as a man's fist. The pedicle of the ovary was clamped and ligated with catgut and the ovary removed. The adhesions were very slight. The cut surface of pedicle was small and was not covered by suturing, neither was any chemic substance dusted upon the stump, or used to cauterize it. The appendix showed evidences of a chronic inflammation and was removed, and the stump treated according to Doyen's method. The right ovary contained a cyst about 2 cm. in diameter. This was excised and the wound in the ovary approximated with catgut. The uterus was retroverted and somewhat prolapsed, and a ventrosuspension was done by Kelley's method. The abdominal wound was closed by a figure eight of silkwormgut tied over a roll of gauze. Before the deep sutures were tied the skin was approximated with a subcutaneous suture of silkwormgut. The patient made a rapid and uneventful recovery. On the ninth day the sutures were removed, and the wound was found united and clean. On the thirteenth day she was awakened by a quite severe pain in the left groin. This continued, and about 4 hours later the entire extremity began to swell. The limb was elevated and hot applications applied. The pain gradually extended to the knee, and then to the calf of the leg. It was not severe, and in 36 hours had disappeared. There was no change at any time in the pulse-rate or temperature—both remained normal. I was at a loss to explain the cause of the thrombosis. Physical examination revealed nothing abnormal. The heart, lungs, and kidneys were found to be in the same condition as they were before the operation. Vaginal examination was negative. The patient's right kidney was very movable, and we had decided to anchor it about 10 days after performing the first operation. This plan was now abandoned. The subsequent history of the case is as follows:

On the twentieth day following the operation the limb had returned to its natural size. On the twenty-second day the patient got out of bed and sat in a chair. From this time she began to walk about. The limb still swells and becomes painful when used. The patient wears a rubber stocking and gets along very well, but there has been no improvement in the leg during the last 18 months. The patient's general health has

remained good. I anchored the right kidney 9 months after the first operation. Since that time the only complaint that the patient has is of the leg—this does not improve.

I have personal knowledge of a thrombosis of the left femoral vein following an interval operation for appendicitis in a man of 33. The wound healed by primary intention. This patient was operated upon about a year ago, and the symptoms correspond to the case herewith reported.

E. R. Secord reports in the *Montreal Medical Journal* a case of double inguinal hernia in which the symptoms of thrombosis of the left femoral vein occurred on the twelfth day following the operation. Both operation wounds were clean. Secord has arrived at the following conclusions concerning the condition:

1. That no one etiologic factor is alone responsible for the occurrence of this complication.
2. That the rate of infection in otherwise noninfective cases does not appear to be an important one.
3. Conditions of sudden decrease of pressure dependent on the operation probably have a causative influence.
4. Treatment should be prophylactic, as by avoidance of unnecessary traumatism, or hemorrhage, or of suddenly decreased tension, as by having the wound area well supported by firmly applied dressings.
5. So far as the author is aware, there has been no mortality in the reported cases, but the occurrence of pulmonary embolism in a certain proportion warns us that this termination is not an impossible one.

I am in accordance with Secord's views in regard to this condition; but, so far as I can determine, we know absolutely nothing concerning the cause or nature of this complication. If a mild infection was present in these cases, we have no proof of it; if the iliac or femoral vein was injured, the injury was certainly slight. Injury to the vessels would seem improbable in the case that I have reported and in the one following the operation for appendicitis.

I believe that no advice can be given concerning the etiology, prophylaxis, or treatment of thrombosis in noninfected patients until a larger number of cases has been reported and the conditions studied more closely from both a clinical and pathologic standpoint.

FORMATION OF THE RED BLOOD CORPUSCLES IN THE SPLEEN AND LYMPHATIC GLANDS.

BY

EPHRAIM CUTTER, M.D.,

of New York City.

To my knowledge, the first successful researches were made by Salisbary in 1850 on living birds, cats, dogs, fishes, horses, opossums, oxen, pigs, raccoons, reptiles, sheep, and other species. See paper published in the *Journal of the American Medical Association*, April, 1866. The writer then studied the living spleens of frogs and turtles, in all cases verifying the formation of the red blood corpuscles. He also found red corpuscles in the blood of the trout, and with Dr. G. B. Harriman photographed it, and in 1877 demonstrated them to the American Medical Association.

The matter to be settled is as to the human spleen. When Guiteau was sentenced to death, I proposed that his spleen might be used to settle this question, as his sin was so great in killing President Garfield. For this I was abused.

Dr. H. O. Marcy, ex-president of the American Medical Association, will vouch that I have asked him to examine the blood of a living human spleen or send it for examination dried in a film on a slide. I would hence cordially endorse the plea of Dr. E. T. Williams that this be done. In the multiplicity of laparotomy cases and in the present fearlessness of opening the peritoneal cavity, that surgeons might gratify this plea and complete the history.

Lymphatic Gland.—The nearest I have come to the formation of the red corpuscle in living man was in a case of lymphatic gland abscess at the right angle of the lower jaw. Here in the discharge were found at different times white corpuscles with red corpuscles inside.

NEW DEVICE FOR ADMINISTERING ETHER.

BY

ALFRED HEINEBERG, M.D.,

of Philadelphia.

Many of us have experienced inconvenience while etherizing during operations on the neck, head, kidney, etc., in which the patient's head is turned to one side. This is particularly true if an ether cone like the Allis' is used.

Without removing the cone from the patient's face and perhaps disturbing the operator it is almost impossible to deliver the ether upon the cone in such a manner as to prevent a large portion of the anesthetic being lost by escaping from the lower surface of the cone. The apparatus here illustrated obviates this difficulty. It embodies no new principle, is simple, easy of construction and manipulation. Its use in the Jefferson Hospital during the last year has demonstrated its value.

The apparatus is manipulated by one hand as an atomizer, and ether in any quantity can be directed from a bottle upon any part of the cone desired.

A, a rubber stopper to fit an ordinary 58 ounce bottle. It has 2 perforations to admit the glass tubing B and C, $\frac{1}{2}$ inch in diameter. The long arm of C should reach to the bottom of the bottle. The bore at the tip X must be narrowed to the diameter of a pin, which is easily accomplished by holding the short arm of C almost vertically over a Bunsen flame. D, a piece of rubber tubing connecting B and E, a section of a quill, which in turn is inserted into the nozzle of a soft rubber ear syringe, G. At F the quill has a pin-point perforation which is very important for without it the stream of ether cannot be controlled by pressure on the bulb.

FINGER INJURIES AND EPILEPSY.

BY

W. P. SPATLING, M.D.,

of Sonyea, N. Y.

To the Editor of *American Medicine*:—In the December 19, 1903, issue of *American Medicine*, page 947, you mention "Epilepsy from Bruise of Finger." It appears that an employee of a manufacturing company who had a finger injured in a stamping machine, developed "traumatic epilepsy," and sued the company for \$5,000. It also appears that "a nerve running from the end of the finger to the brain was lacerated."

About 5 years ago, a man—an eddyite, by the way—consulted me about his son, a boy of 9, who was said to be a victim of epilepsy, being accustomed to have 6 to 8 mild attacks every day. I never saw the boy while he was in a seizure, and cannot vouch for the correctness of the diagnosis made by the father in the case. I advised that the boy be sent to the country to live on a farm. This was done, and a month later I received, in response to an inquiry, a letter from the father as follows:

"I followed your advice, and brought my son up here and put him on a farm. I am happy to state that he has entirely got rid of his attacks. He has had none since the day he was playing with a lawn-mower and accidentally cut off one of his fingers."

So far as finger injuries in "causing" and "curing" epilepsy are concerned, it seems a poor rule that won't work equally as well both ways.

ORIGINAL ARTICLES

AMPUTATION AT THE HIP-JOINT FOR SARCOMA, WITH A REPORT OF SEVEN CASES, WITHOUT MORTALITY; SUBSEQUENT HISTORY OF PATIENTS.*

BY

WILLIAM B. COLEY, M.D.,

of New York City.

During the past 14 years I have observed 17 cases of sarcoma of the femur, and 22 cases of sarcoma of the thigh. The majority of these cases were hopelessly inoperable when they came under my care, but in 11 cases I performed high amputation. In 7 instances the amputation was made through the hip-joint, and in 4 cases just below the trochanter. It is to the results, immediate and remote, in these cases that I would especially call your attention.

In my 7 cases of hip-joint amputation the sarcoma started in the bone or periosteum in 5 cases, and in the muscles or fascia in 2 cases. The ages of the patients ranged from 6 years to 60.

FEMUR CASES.

Male.....	6 years.
Female.....	11 "
Female.....	13 "
Male.....	45 "
Female.....	60 "

THIGH CASES.

Female.....	24 years.
Male.....	49 "

CASE I.—*Small round-celled sarcoma of the femur, periosteal; hip-joint amputation.* E. S., male, aged 6. No history of trauma. In February, 1898, the patient's mother noticed a small lump in the right femur. This increased in size slowly for 3 months, and then grew very rapidly. I first saw the patient in May, 1898, with Dr. W. R. Townsend. There was a wellmarked fusiform swelling, involving the lower third of the thigh, and undoubtedly connected with the femur. The skin was normal in appearance, and freely movable over the swelling. The joint was not involved; no enlarged glands of any size in groin; no signs of metastasis. The general character of the tumor with the history of rapid growth, made the diagnosis of sarcoma clear. Amputation was strongly advised, but the parents refused to consent. Six weeks later I again saw the patient in consultation, and at this time the parents consented to operation, although the tumor had increased so greatly in size that the prognosis was much more grave. Operation was done September 6, 1898, 7 months after the tumor was first noticed. Dr. Wyeth's pins were used with greatest satisfaction; scarcely a dram of blood was lost. The patient suffered little from shock, and made an excellent recovery. Four months later the patient died of generalization with metastases in the lungs.

CASE II.—*Round-celled sarcoma of femur, periosteal; hip-joint amputation.* F. N., aged 11, a female. Family history good. In February, 1897, the patient fell down a flight of steps and injured the right knee; a slight swelling developed accompanied by pain which continued and increased. Three months later a wellmarked swelling was noticed on the inside of the knee. This grew very rapidly; still the patient continued to get about. She visited various hospitals, and was treated for various diseases, *e. g.*, tuberculosis and syphilis. She came under my observation on July 28, 1897, 5 months after the injury. At this time the clinical diagnosis of periosteal sarcoma was beyond question. The circumference of the left femur over the most prominent part of the tumor was 6 inches greater than that of the opposite side. Hip-joint operation was immediately performed at the Post-Graduate Hospital with the assistance of Wyeth's pins. The patient suffered very little from shock, and made an uninterrupted recovery. She returned to her home in New Jersey, and has since been lost sight of, although the utmost efforts were made to trace the subsequent history.

CASE III.—*Osteochondrosarcoma of the lower end of the femur; hip-joint amputation.* L. Z., aged 13, a female, was admitted to the New York Cancer Hospital, May 30, 1898. Family history good. There was no history of trauma. Intermittent pains in the lower end of the femur were the first symptoms; supposed to be an attack of rheumatism. Shortly afterward a small swelling was noticed in the region of the pain. There was no interference with the movements of the joint, the swelling being situated just above the condyle. The patient was referred to me by Dr. W. R. Townsend in May, 1896. Although

the patient was at that time under treatment for possible specific disease, the diagnosis of sarcoma of the femur was made and amputation at the hip-joint advised. The family seriously objected to so severe an operation, and only consented after a small portion of the tumor had been removed by a Mixer punch, under cocaine, and proved to be chondrosarcoma by microscopic examination. Amputation at the hip-joint was performed in June, 1898, less than 6 months from the time the disease was first noticed. Wyeth's method was used also in this case. The patient lost little blood, and made an excellent recovery. She remained perfectly well for nearly a year, when she began to fail in health, losing in weight, and slowly becoming cachectic. There was no local return of the disease, but evidently generalization in the internal organs had taken place. She continued to fail, and died in May, 1900, 2 years after the operation.

CASE IV.—*Osteosarcoma of the femur; hip-joint amputation.* T. B., a male, aged 45, blacksmith. Family history good. January 29, 1900, he received a fracture of the lower end of the left femur from the kick of a horse. The fracture was a simple one, and was treated with extension and weights for 6 weeks, with apparently good union. Two to three months later the patient noticed what he thought was an unusual enlargement at the site of the fracture. This was regarded by the physician attending him as callus. It, however, slowly increased in size, and finally became painful. The patient came under my observation on August 21, 1900. At this time examination showed the lower end of the femur the site of a tumor the size of a child's head, with smooth outlines, firmly fixed to the bones; the joint was not involved; skin was freely movable and normal in appearance. The tumor was firm in consistence. The diagnosis of sarcoma was made, and amputation at the hip-joint advised. This was performed on August 29, 1900. I made use of Wyeth's method with most satisfactory result. The patient made an uninterrupted recovery, but 6 months later returned with unmistakable evidence of metastases in the lung; he continued to grow worse, and died within a year.

CASE V.—*Periosteal sarcoma of the femur; periosteal hip-joint amputation.* Mrs. D., aged 56. Family history good. She had no previous trauma. Toward the end of 1900 the patient first noticed a hard lump about the middle of the left thigh. She was not sure whether the tumor was movable or not. About 1½ years ago the growth was removed at the Mt. Sinai Hospital. It recurred about 6 months later. The patient was admitted to the General Memorial Hospital in January, 1903, and at this time there was a large tumor occupying the anterior aspect of the upper portion of the left thigh. The tumor was in 2 sections, nearly coalescing at the base, the lower portion being about the size of a fist, the upper considerably larger, slightly movable, and apparently attached to the periosteum; the skin was normal. The patient was treated with the mixed toxins and Röntgen ray for 3 months, without any appreciable effect upon the size of the tumor. She returned to her home, and in October the tumor had increased considerably in size, and extended to, and beyond Poupert's ligament. Her general condition was bad; she was markedly anemic, and had lost considerable weight. Pulse was rapid—120, and weak. In view of the fact that the tumor extended so high up, and her general condition was so bad, the prognosis after hip-joint amputation was considered very grave, and operation was not urged. After a consultation it was, however, decided to operate, and hip-joint amputation was performed on October 20, 1903. Preliminary ligature of the external iliac was done, and amputation performed with almost no loss of blood. The wound was closed by a long posterior flap. The patient made an excellent recovery, with the exception of some sloughing of the distal portion of the long flap.

CASE VI.—*Spindle-celled sarcoma of the thigh; hip-joint amputation.* M. L., female, aged 24. Family history good. For some years she worked many hours a day on a sewing machine, during which time her right thigh rested upon the edge of a hard chair. In the fall of 1898, she noticed a hard lump apparently in the muscles of the right thigh, just at the point where the thigh had rested upon the chair. This lump grew rather rapidly, and she was operated upon by Dr. Bull at the New York Hospital, on December 29, 1898, 2 to 3 months after the tumor had first been noticed. Microscopic examination showed the growth to be a mixed-celled sarcoma, spindle and round. The tumor recurred quickly after operation, and the patient was referred to me by Dr. Bull on January 25, 1899, with a diffuse local recurrence, 3 in. by 5 in. in diameter. She was put on the treatment with the mixed toxins with the result that the tumor and induration entirely disappeared. It, however, soon returned, and again began to increase in size in spite of continued treatment with the toxins. I advised amputation at the hip-joint, and performed the operation in September, 1899. Wyeth's pins were used. The patient suffered very little from shock, and made an excellent recovery. No further treatment with the toxins was given after the operation. The patient remains well up to the present time, over 4 years since operation.

CASE VII.—*Spindle-celled sarcoma of the left thigh; hip-joint amputation.* W. V., a male, aged 49. His mother died of cancer of the uterus 25 years ago. The tumor was first noticed in the anterior portion of the left thigh, in the summer of 1896. There was no history of trauma. The tumor gradually increased in size. On August 31, 1897, an extensive operation was per-

* Read before the Southern Surgical and Gynecological Association, at Atlanta, December 16, 1903.

formed by Dr. J. D. Bloom, in New Orleans. Microscopic examination showed it to be a spindle-celled sarcoma. The tumor recurred in May 1898, 9 months after the operation. The patient was referred to me by Dr. Bloom for the toxin treatment, which was tried very thoroughly from July to October 1898. At first there was marked improvement and considerable diminution in size. Improvement then ceased, and after remaining stationary for a time, the growth began to increase again. High amputation at the hip-joint by Wyeth's method was done in October, 1898. The patient remained well until the summer of 1900, when he had a recurrence, which proved fatal in the latter part of 1900, 2 years after the hip-joint amputation. The entire duration of the disease in this case was about 4 years.

Method of Operation.—Wyeth's method of wire pins was used in all but the fifth case, in which the tumor extended up to Poupart's ligament, making it impossible to use the pins. In this case I first tied the external iliac artery above Poupart's ligament and then disarticulated. No anterior flap could be made, and it was necessary to depend upon a long posterior flap. The patient, though 56 years of age and very weak and anemic, stood the operation very well, and suffered a minimum of shock. She lost practically no blood at the operation, and made an excellent recovery. A portion of the long flap sloughed, but did not become infected. The time of operation in this case was 35 minutes, not materially different from the length of time required when Wyeth's pins were used. One advantage noticed in this case was the absence of oozing, so often seen when the thigh has been tightly constricted by rubber tubes or bandages.

In addition to the foregoing 7 cases of hip-joint or high amputation, I have done 4 amputations below the trochanter, as follows:

CASE I.—*Periosteal round-celled sarcoma of the lower end of the femur.* Mrs. S. R., aged 26; family history good. She was well until the spring of 1895, when she fell and dislocated the right patella. The knee remained more or less stiff afterward. Several futile attempts were made to break up the adhesions, under ether. In December, 1896, a swelling was noticed on the inner side of the thigh just above the condyle, accompanied by slight pain. The tumor increased slowly in size and 2 months later an exploratory incision was made by Dr. George A. Plimpton, under ether, and a portion of the tumor removed for microscopic examination. The latter was made by Dr. H. T. Brooks, of the Post-Graduate Hospital, and showed the growth to be a mixed-celled sarcoma, very rich in cells and apparently highly malignant. A specimen was also examined by Dr. B. H. Buxton, of the Loomis Laboratory, who pronounced it an alveolar sarcoma, composed principally of round cells, very malignant.

In April, 1897, the patient was referred to my service at the General Memorial Hospital, at which time the exploratory incision had not yet healed and there was free discharge of pus coming from the bottom of the wound; there were several enlarged glands in the groin. One of these was removed under cocaine, and proved to be nothing but hyperplasia.

April 5, 1897, amputation at the middle of the thigh was performed and all the glands in the groin were removed. Examination showed them not to be involved. Examination of the tumor showed it to be of periosteal origin, the central portion of the bone not being invaded. There was considerable suppuration in the end of the stump, but as the leg was infected at the time of the operation, this was not surprising. The patient made a good recovery, but died 4 months later, of internal metastasis, chiefly in the lungs.

CASE II.—*Melanotic, round-celled sarcoma of the thigh; amputation just below the trochanter.* Mr. W., aged 55; family history good; no specific or tuberculous history; for a number of years he had a small, pigmented mole on the inner aspect of the right thigh, just above the knee. In January, 1901, the mole became irritated by his clothing and occasionally bled. Shortly afterward it began slowly to increase in size. A few weeks later he noticed enlarged nodules in the groin, but little attention was paid to them. They increased gradually in size, and early in July, a mass of glands, the largest the size of a goose egg, was removed from the groin by his physician, Dr. Stuart, of Pittsburg. Macroscopic as well as microscopic examination showed the mass to be typical melanotic, round-celled sarcoma. Two smaller masses removed from the inner aspect of the thigh, about midway between knee and groin, showed the same type of growth. In July, the patient was referred to me by Dr. Stuart, for the toxin treatment, and from July to October received daily injections of the mixed toxins. At the time the treatment was begun, there were numerous small nodules, varying from the size of a No. 8 shot to that of a split pea, almost entirely encircling the lower portion of the thigh just above the knee and scattered about the various areas nearly up to the groin. At first there was some decrease in the

size of the small tumors, but later they began to increase in size and in number. The patient also began to lose flesh and appetite. On October 10, after consultation with Drs. Bull, Bryant, and Hartley, it was decided to amputate just below the hip, not with any hope of getting rid of the trouble, but expecting that, by taking away the largest focus of the disease the end might be more comfortable. Amputation just below the trochanter was done, Wyeth's pins being used. The patient made a good recovery and gained considerably in weight until the latter part of November, when a small tumor appeared in the skin of the abdomen. The patient again began to lose flesh and weight and showed evidence of general metastases. His condition became worse rapidly and he died 4 months later.

CASE III.—*Sarcoma of the thigh; amputation just below the trochanter.* Mr. I. N. S., aged 41, was referred to me on June 28, 1899, for sarcoma in the middle of the right thigh. The patient was a large, powerfully built man, 6 feet tall, weighing about 200 pounds; he had been in perfect health up to a few months prior to this time; there was no history of trauma.

Physical examination showed a fusiform swelling, deeply seated, apparently attached to the bone, but not a part of it; not movable. I made an incision under ether, and found a tumor of about the size of a goose egg, situated beneath the muscles, apparently arising from the periosteum; it did not involve the bone proper, and was easily separated from the femur. All the tumor tissue was apparently removed, and the patient was put upon the toxins to prevent a recurrence, if possible. However, in September, 1899, there was unmistakable evidence of a local return, and on October 3, 1899, I performed amputation just below the trochanter, making use of Wyeth's pins. The wound healed by primary union, and the patient made an excellent recovery. The toxins were given after he returned to his home in New Orleans, and he remained fairly well for about a year. In December, 1900, there was a recurrence in the stump and sciatic nerve. For this, further amputation was performed with disarticulation of the small fragment of bone remaining from the first operation, by Dr. Bloom, of New Orleans. The patient remained well, and had no local recurrence, but in May, 1902, I received a letter from Dr. Bloom, stating that the patient was confined to his bed with left pleural metastasis. He died shortly after this. The entire duration of life since the beginning of the disease was 3½ years.

CASE IV.—*Spindle-celled sarcoma of the thigh, recurrent, after primary sarcoma of the metatarsal bone; amputation just below the trochanter.* F. K., female, aged 16, had a fall in 1888, injuring her right foot. Shortly afterward 2 lumps appeared at the site of the injury; the following year the tumors were removed by Dr. William T. Bull, at the New York Hospital, with excision of the third and fourth metatarsal bones. She remained well for 3 years after that when she received another injury to the foot, followed by local recurrence. Syme's amputation was performed by Dr. Bull. In 1893 she fell downstairs again, injuring the stump and almost immediately afterward a tumor appeared on the site of the injury; this slowly increased in size; shortly after this a large tumor, the size of a child's head, developed in the popliteal space. This was removed in 1894 by Dr. Bull. Microscopic examination of all these growths showed them to be spindle-celled sarcoma. At the time the popliteal tumor was removed, the small tumor in the stump was left behind and treated with the mixed toxins, with the result that it entirely disappeared. About 1½ years later there was a local return and also a return in the lower part of the thigh, for which I performed high amputation just below the trochanter in 1896. Shortly after there was an extensive recurrence in the gluteal region, which was partially removed by operation, and the patient was put upon the mixed toxin treatment, which was kept up at intervals for 3 years.

I examined the patient in June, 1903, and as she was very anxious to get a false leg, I decided to remove the small tumor that had remained since the last operation, and which had shown no tendency to increase in size. This was believed to be merely fibrous tissue, and such it proved to be on examination after removal.

The patient is in perfect health at present, 9 years since the beginning of the treatment, and 7 years after the last operation.

The question of the curability of sarcoma of the femur by operation is one that is still more or less unsettled. Butlin, in his wellknown book upon sarcoma, states that of 68 cases in which treatment consisted of hip-joint or high amputation, only one patient was known to live more than 3 years.

My own observation bears out his opinion that sarcoma in this locality represents one of the most malignant forms of tumor with which we have to deal.

Of my 5 patients with sarcoma of the femur treated by hip-joint amputation, two died within a year, one lived two years, one was not traced, and the last, a recent case, is the only one in which the patient is known to be alive.

The 4 patients with sarcoma treated by high amputation just below the trochanter, one with sarcoma of the

femur, died 4 months afterward of lung metastases; the second, with sarcoma of the femur, had a local recurrence at the end of 1½ years; disarticulation was then performed, and the patient lived for 2 years longer, when he died of generalization of the disease; the third case in which amputation below the trochanter was performed, was a multiple melanotic sarcoma of the skin of the thigh, the patient died 4 months later of generalization and internal metastases; the fourth case was a recurrent sarcoma of the thigh, primary in the tarsus; there was a local return in the gluteal region, which disappeared under the use of the mixed toxins. The patient is alive and well at present, 6 years after amputation.

The cure of sarcoma of the femur (by high amputation) is so rare that every success should be reported. The only successful cases that have come within my immediate knowledge, are the following, six in number:

CASE I.—*Osteosarcoma of the femur; amputation at the hip-joint by Dr. Wm. T. Bull, at the New York Hospital.* Amputation was done 16 years ago. The patient contracted septic infection of the stump. There was continued high temperature—probably streptococcus infection—from which, however, he recovered and was well six years afterward.

CASE II.—*Sarcoma of the femur; amputation at the hip-joint by Dr. W. L. Robinson of Danville, Va.* The patient was put upon a course of the mixed toxins immediately after the operation in the spring of 1898. He remained well for more than three years, when he developed a recurrence in the iliac fossa, which broke down and disappeared under the resumption of the toxins.

CASE III.—*Periosteal sarcoma of the lower end of the femur; amputation at the hip-joint by Dr. J. D. Rushmore of Brooklyn.* The operation was done 6 years ago and the patient was well when last heard from, over 5 years after operation.

CASE IV.—*Giant-celled sarcoma of the femur; patient of Dr. A. Gerster of New York.* The microscopic examination was made by Dr. Mandelbaum, Pathologist to Mt. Sinai Hospital and the diagnosis confirmed by Professor T. M. Prudden, but the case was considered too far advanced by Dr. Gerster for hip-joint amputation. The toxins were, therefore, decided upon and after prolonged treatment at the Montefiore Home for Incurables, the tumor disappeared. The patient was exhibited before the New York Surgical Society in November 1903, by Dr. John Rogers, more than 4 years after the treatment. The patient was in perfect health and there was no sign of either local or general recurrence.

CASE V.—*Osteosarcoma of lower end of the femur; amputation at hip-joint by Dr. D. Hayes Agnew of Philadelphia, 16 years ago.* The patient, a prominent physician of Philadelphia, is still alive and well.

CASE VI.—*Periosteal sarcoma of the femur; amputation at the hip-joint by Dr. George W. Shrady of New York.* The patient is alive today, 21 years after amputation.

It is interesting to note that in one of these 6 cases no amputation was done, as the disease was considered too far advanced for amputation by Dr. Gerster, and the patient was treated for some months with the mixed toxins of erysipelas and *Bacillus prodigiosus*, with the result that the tumor finally disappeared and the patient is at present quite well with perfect use of the leg, 5 years afterward. In this case the diagnosis was made by Dr. Mandelbaum, pathologist to the Mt. Sinai Hospital, and confirmed by Dr. T. Mitchell Prudden of the College of Physicians and Surgeons.

In another case (Dr. Bull's) in 1886, the patient had severe septic infection following operation, with continued high temperature for some time. In this case there was probably a streptococcus infection which, I believe, had much to do in destroying any sarcomatous cells that might have been left behind and caused a recurrence. It is worthy of special note that also in one of my own cases of sarcoma of the thigh, the patient who is still alive more than 6 years after operation, the mixed toxins were used for several months prior to amputation. I believe the malignancy in this case was much modified by the toxins, and hence, recurrence was prevented.

In the discussion of Dr. Wyeth's¹ paper on "Hip-joint Amputation for Sarcoma," at the Philadelphia Academy of Surgery, in 1901, I stated that the end results of operation for sarcoma of the femur and of the

long bones in general in the preantiseptic days, as shown in the classic papers of Gross,² were much superior to those obtained today. The explanation that I then offered, and the only one that seems plausible is that the streptococcus infections that not infrequently occurred in the earlier period, destroyed the sarcoma cells that were left behind and prevented a recurrence.

If this be the true explanation we have rational ground for advising a thorough course of erysipelas toxin treatment, as a prophylactic after all cases of primary amputation. The prophylactic value of the mixed toxins is proved by the case of Dr. Robinson and by several of my own cases. In one case I removed, under cocain, a tumor of the finger. The clinical diagnosis was uncertain, but the microscopic diagnosis by Professor William H. Welch and three other pathologists proved it to be a mixed-celled sarcoma of periosteal origin. The question of the removal of the finger was carefully discussed, as it was practically certain that some of the diseased tissue had been left behind. It was finally decided to put the patient upon a course of toxin treatment which was continued with intervals for more than a year. The patient is still well and free from a return, 3½ years later.

To return to the question of operation for sarcoma of the femur, there is a difference of opinion as to what is the best method. While the weight of surgical opinion has long been in favor of high amputation or amputation through the hip-joint, at the discussion in Philadelphia referred to, Dr. Bloodgood, of Baltimore, spoke in favor of resection of the bone instead of amputation and cited the experience of Mikulicz³ in support of this view.

I have carefully gone over the cases reported by Mikulicz and I do not believe they warrant us in giving up amputation.

Mikulicz refers to one case of von Bergmann, of resection of 15 cm. of tibia and fibula. The patient recovered, with very fair use of his leg. As to the later history of this case, nothing is stated.

One case of Bramann, of resection of 10 cm. of the head of the tibia for myeloid sarcoma, with patient well 3 years later.

Mikulicz's own cases of resection of long bones for sarcoma were 7 in number:

Two of the radius; time of observations, 1½ year in one; 4 months in the other case.

One of ulna; well 2 months after operation.

One of tibia; well six months.

Two cases of spindle-celled sarcoma of femur, periosteal.

1. Resection of 20 cm., patient well, can walk without cane, over a year after resection.

2. Resection of 20 cm. for periosteal spindle-celled sarcoma of femur. Resection unsatisfactory to patient and amputation preferred 5 months later. (Amputated leg shows no trace of recurrence; at both bony ends, copious new formations of bone.)

Mikulicz's concluding remarks are briefly as follows: "In view of the foregoing I can recommend to you, in future, to try resection instead of amputation in malignant disease of the long bones; of course, with the necessary limitations and precautions."

He further mentions as an important advantage of resection over amputation the fact that patients may be easily persuaded to have such an operation done at a time when they would refuse amputation which, when finally consented to, may be too late.

While the cases reported by Mikulicz may prove that it is possible to resect the femur in many cases of sarcoma, and in some instances to give the patient a fairly useful limb, they are very far from proving that the patients can be cured of the disease by such an operation.

The procedure might, perhaps, be worthy of a trial in slowly-growing myeloid sarcoma of the tibia, the radius and ulna, but to extend it to periosteal sarcoma of the femur, I believe would be most unwise. In the

*An unpublished case communicated to me by Dr. S.

latter case the disease is so highly malignant and extends so far beyond the macroscopic limits, that it would be almost impossible to be sure of its entire removal by resection.

One of the cases of sarcoma of the lower end of the femur, in which Dr. Bull performed hip-joint amputation, the bone at first was sawed through about 6 inches below the trochanter, then feeling doubt lest the disease had extended higher, disarticulation was performed. A careful examination of the upper end of the bone was made by Dr. B. H. Buxton, and it was found that the sarcoma cells had extended upward to the head of the bone, although the gross appearance was normal.

In such cases, resection would prove of little value.

The chief danger in sarcoma of the femur lies in the remarkable tendency to early metastasis. This is especially true of periosteal growths. In many cases, I believe, a generalization of the disease has already taken place before the operation. Hence the importance of making a very careful physical examination of the entire body, especially of the lungs. It is often recommended to make an exploratory incision into the tumor prior to an operation for the sake of diagnosis. This custom, I believe to be attended with grave peril to the patient. Such incisions into sarcoma of any locality may cause the infectious sarcoma cells to enter the blood-current and be carried to remote parts of the body to be the starting point of metastatic tumors. In sarcoma of the femur the risk is, I believe, especially grave. In none of my own cases have I felt this necessity of such exploratory incisions, and I believe that a careful history of the case and a careful physical examination of the tumor will almost invariably make the diagnosis clear. In cases of doubt I would have the patient prepared for operation, an Esmarch bandage applied, ready for amputation, and then cut into the tumor. The gross appearance will, as a rule, dissipate the doubts, but if not, a frozen section can be examined.

The Value and Place of the Röntgen Ray or Toxins in Sarcoma of the Femur.—An important question comes up as to the propriety of trying the Röntgen rays or toxins before advising such a serious operation as hip-joint amputation.

Personally, I do not think we are justified in allowing the patient to run the risk of a generalization of the disease, which may easily take place during the few weeks necessary to determine the success or failure of such treatment. I have never advocated the use of the toxins in sarcoma of the femur, always advising immediate amputation, and yet, in sarcoma of other long bones, I think a preliminary course of toxin treatment might be justifiable. In support of this opinion, I would cite a case of recurrent sarcoma of the tibia, in which microscopic examination was made and the diagnosis confirmed by Professor John Caven, of the University of Toronto. In this case, before amputating, I treated the patient for 3 months with the mixed toxins, in large doses, with the result that the large tumor entirely disappeared. The patient is today in perfect health, working on a farm in Canada, 6 years after treatment.

In regard to the Röntgen ray, we are not justified with our present knowledge, in assuming that an osteosarcoma of any kind, much less a sarcoma of such rapid growth and high malignancy as sarcoma of the femur, can be permanently cured with the Röntgen rays. On the other hand, it would be unfair and unscientific, not to mention one remarkable result obtained by myself in a case of sarcoma of the femur.

The Röntgen rays were begun in February, 1902, after the patient and his family had absolutely refused considering an operation.† Almost two-thirds of the lower end of the left femur was occupied by a typical round-celled sarcoma of rapid growth. The diagnosis was confirmed by microscopic examination. The patient has had almost continuous Röntgen ray treatment from February, 1902, to the present time. After a few months the circumference of the left leg became practically normal and the patient regained his normal weight. At the end of nearly a

year he developed extensive metastases in the left pectoral region, which was partially removed by operation, and afterward treated with the Röntgen ray. A little later, or a year ago, he developed a very large metastatic tumor in the right lumbar region, filling up a good part of the iliac fossa. The patient was put upon large doses of the toxins in addition to the Röntgen ray, with the result that the lumbar tumor broke down and was evacuated through a posterior incision. At present, December 4, 1903, the patient weighs 106 pounds, and his general condition is good. There is still some thickening of the left femur; the sinus remains open and there is slight discharge. There is no recurrence apparent, either in the pectoral or lumbar region. Nearly 2 years have elapsed since the Röntgen ray treatment was begun and 1 year since the toxins were added. He is at present taking the Röntgen ray 3 times a week.

In this case it is impossible to deny, that the Röntgen ray alone and unaided, almost destroyed the primary local sarcoma in the femur. It, however, did not prevent, and possibly may have aided generalization of the disease in the formation of metastases referred to. Although the boy's present condition is fairly good, we cannot regard him as cured, and in all probability further metastases will occur and prove fatal.

CONCLUSIONS.

1. Sarcoma of the femur is a malady so dangerous to life, so prone to early metastasis, that only the most radical operation should be performed, and that at the earliest possible moment.
2. Hip-joint amputation is to be preferred to resection or to amputation through the shaft.
3. Recurrence being the almost invariable rule after all methods of operation, a thorough course of mixed toxin treatment after operation, as a prophylactic, offers the best hope of permanent cure.

CAN OUR PROCEDURES FOR THE JUDICIAL DETERMINATION OF THE CAUSE OF DEATH BE BETTERED?*

BY

SOLOMON SOLIS COHEN, M.D.,
of Philadelphia.

The cause of the death of a certain person may assume great importance in a judicial procedure. Such procedure may be either civil or criminal. Among civil issues may be mentioned suits against insurance companies, suits for damages against employers, and litigation over inheritances. Criminal procedures involve the question of homicide in its various degrees, together with the possibilities of suicide. No one who has been consulted, or has testified, in such cases can feel satisfied that the method for the judicial determination of the cause of death pursued in the Courts of Pennsylvania, and probably in most other Courts of the United States, is that best calculated to elicit or to elucidate the truth; or that a jury selected in the ordinary manner, and having the issue presented to it according to the customary method, can be expected to arrive at an intelligent decision in a case of any degree of obscurity. I have, indeed, in a number of civil causes advised attorneys to counsel their clients to settle out of court rather than attempt to make plain to a jury what seemed to me to be the true facts involved. It will be observed that I do not assert that juries cannot arrive at a correct verdict. It is quite possible that they often guess right. On the doctrine of chances they will, indeed, guess right in 50% of the cases—and guess wrong in the other half. The same chances, however, pertain to the flipping of coins, or the drawing of straws. Our civilization should be able to find some method with larger possibilities of arriving at the truth. A certain degree of difficulty is,

* Read before the Medical Jurisprudence Society of Philadelphia, November 16, 1903.

indeed, inherent in the subject itself, and to that degree the possibility of error is irremediable. Our present possibilities of error, however, are not due solely, or even chiefly, to this essential obscurity, but in greater part arise out of antiquated and cumbrous forms of procedure. The development of the law has not kept pace with that of the medical sciences, and its present methods, while probably fairly adequate to the ordinary transactions of life, cannot be applied to issues in which questions of advanced science must be considered.

In order to simplify this paper, I shall not discuss the subject from the viewpoint of legal principles or of constitutional guarantees. It is quite possible, therefore, that what I shall say is, from such points of view, subject to qualification and modification. Nevertheless, a certain familiarity with the methods of courts, and that acquaintance with constitutional principles which belongs to the ordinary American citizen have, I think, prevented me from falling into any gross error in this respect; so that the modifications and qualifications required will probably concern matters of detail rather than questions of fundamental principle. I am compelled to assume, however, an hypothesis, which I am afraid does not always conform to the facts in the concrete case, namely, that it is the object of the court, and of all its officers, including therein the counsel upon both sides, to bring out the truth. Accordingly, the method herein to be proposed for the determination by judicial procedure of the cause of death in a given case, is confessedly subject to the criticism that it will restrict the opportunities of counsel on either side to exclude from consideration relevant facts unfavorable to the view he may advocate, or, on the other hand, to introduce irrelevant testimony, which may have the effect either of favorably inclining the jury toward his contention, or of so beclouding the issue as to leave the jury in a state of doubt, that it may be his object to produce. If it be the unalienable right of the plaintiff or of the defendant to withhold and to distort material evidence, then the defects of our present methods are incurable, and every proposition for a remedy will have to be withdrawn.

The most important procedure in which the cause of death becomes the subject of judicial inquiry is, of course, a trial for murder; and perhaps, if we select this for illustration and discussion, other causes may be dismissed with a few words. First let us review briefly, and with incidental comment, present methods. Let us assume that a death has occurred in the city of Philadelphia under circumstances leading to an investigation by the coroner. The coroner sends his physician to make a postmortem examination. The coroner's physician, in certain cases—certainly when there is a suspicion of poisoning—removes certain portions of the body, including, as a rule the stomach, so tied as to retain its contents, and these are submitted to a chemist for further study. The coroner holds an inquest, at which such witnesses as he deems fit to summon, with or without the advice and assistance of the police officials and of the district attorney, are examined in such manner as he deems proper. A verdict expressing the belief of the coroner's jury as to the cause of death and as to the person or persons responsible for the death is rendered; and any person accused of complicity in the death is committed for action by the grand jury. Before the grand jury, the district attorney conducts an examination, presenting such evidence as he deems fit to make out a *prima facie* case, and the accused is then held for trial before a petit jury. Before the petit jury, begins the grand struggle on the part of the Commonwealth to establish the guilt of the accused person, and on the part of the defendant's counsel either to establish the innocence of his client, or to show to the satisfaction of the jury that there is a reasonable doubt of his client's guilt. Necessarily, the Commonwealth is called upon to establish affirmatively the cause of the death of the person supposed to have been murdered. In support of this

theory, the physician who made the postmortem examination, and any other physician or chemist who may have made other investigations of the body, or of the contents of the stomach, or of other articles having a bearing upon the case—for example, garments or weapons said to be blood-stained, or substances said to be poisonous—are placed upon the stand and examined by the district attorney in order to bring out affirmatively such facts or opinions as he desires to place before the jury. After this, they are cross-examined by the opposing counsel in order to elicit facts or opinions which may seem to contradict the theory of the Commonwealth, or to test their memory, or their qualifications, or their accuracy, or their methods, or to bring out the possibilities of error involved in their methods. Within due bounds, such cross-examination is necessary and proper. It often happens, however, that the cross-examination is permitted by the Court, and no doubt under present rules, must be permitted by the Court, to assume a very wide range and to cover matters irrelevant to the case in hand and serving to obscure rather than to elucidate the truth. This remark applies with still greater force to the examination and cross-examination of witnesses introduced purely as experts to give testimony on matters of opinion and of scientific knowledge, but not in any part upon matters of fact directly concerned in the case.

Even at the risk of reiterating matters with which we are all familiar, it will be well to take time here to emphasize the important difference between one who comes into court to give expression to an opinion, or to scientific knowledge, and one who comes into court to testify to a matter of fact in the case. The physician who makes the postmortem examination testifies partly to facts and partly to opinions. This is so even though he may not be called as an expert, and his testimony may apparently refer to fact only. For example, such a physician may testify that the kidneys were, or were not, inflamed; or that the lungs were, or were not, tuberculous. Apparently, he is testifying to a fact; in reality, he is testifying to an inference. To give testimony as to fact, he should be required to state the appearances presented to the naked eye or under the microscope, or the results of other methods of examination; and then he would be in position to add that in his opinion these appearances or these results indicated the presence or the absence of inflammation or of tuberculosis, as the case might be. This opinion might properly be questioned, criticised, or opposed by other competent opinion.

On the other hand, the chemist who examines tissues and other substances for the presence or absence of poisons, is often put into the position of apparently testifying to an opinion, when in reality he is testifying to a fact. For example, he may say that having performed such and such manipulations he obtained as the result a certain quantity of a given poison—let us say morphin, or arsenic, or strychnin. This testimony is commonly treated by Court, and counsel, and jury, as the expression of an expert opinion; and from that viewpoint, cross-examination is permitted, which might be perfectly proper were this merely an expression of opinion, but is obviously improper if it be the recital of a fact. Chemistry is one of the definite sciences; and if certain definite manipulations are performed by a chemist and certain definite results obtained, it is not a matter of opinion on the part of any individual chemist, but an absolute conclusion of chemical science, and, therefore, a fact as definite as any other within the range of human observation, that the chemist has obtained some definite substance—arsenic, or strychnin, or antimony, or morphin, or whatever it may be. The chemist is therefore testifying purely to a matter of fact, and not to a matter of opinion or inference, when he states, for example, that he has performed certain chemical manipulations and as a result thereof has recovered from suspected tissues a given quantity of arsenic sulfid or of morphin sul-

fate. His manipulations are more complex than that of the police official who takes out a box from a closet, picks or breaks the lock, removes a false bottom, and finds a revolver or an incriminating paper; but they do not differ from these in any essential particular. Acids and gases, heat and electric currents, are used instead of hatchets and knives and screw-drivers, to remove the substances in which the incriminating material is hidden; but when discovered that material is no less definite than is any other material, and its finding is a fact, not an inference. It is true that special skill and care, and above all, accuracy, are required for the manipulations leading to this discovery; and, therefore, the skill, and care and accuracy of the chemist who has performed the manipulations, the wisdom and the necessity of the manipulations, and the identity of the substances that he has recovered as a result thereof, are properly subject to doubt and to test by orderly judicial method. Of this, more hereafter.

A chemist who testifies as to the methods and results of his examinations of suspected tissues and substances, is usually called upon, however, to give in addition, testimony as to his opinions upon certain hypothetic aspects of the case, and upon such opinions is properly subject to relevant cross-examination. In the case of physicians or chemists who have not examined the body or the tissues or the suspected substances, and who are called upon therefore to testify for the Commonwealth in support of its view, or for the defense in opposition to the Commonwealth's view or to the opinions of the Commonwealth's witnesses, the testimony in so far as it bears directly upon the case is entirely of opinion and not at all of fact. Such witnesses, however, are often questioned as to facts of scientific knowledge, as to cases of which they have heard or read, or as to relevant, and sometimes irrelevant, facts within their own professional experience and observation. Testimony of this character should be clearly differentiated from testimony given in answer to hypothetic questions; or in answer to questions calling for opinions upon the case under trial. In their answers to the latter class of questions, expert witnesses must assume that the facts upon which these questions are predicated are true and their opinions are rendered accordingly. The answers to certain questions, therefore, may not have any real bearing upon the issue, whether as to the cause of death or any subsidiary question related therewith, or as to the opinions of witnesses on the other side. It is in this manner that expert witnesses as to opinions or as to scientific facts only, are frequently made to appear to contradict each other, when in reality there is no conflict of opinion or of testimony. Let us suppose that expert A testifies for prosecution and gives a certain opinion based upon the facts submitted to him, he having no knowledge of the facts other than this. Expert B is called to the stand for the defense. The question submitted to him either includes something that was not included in the question submitted to expert A, or, more frequently, omits some vital datum, or may indeed refer to a different phase of the question, and in consequence his answer differs from that of the former witness. When exactly the same question is submitted to two truthful and well-informed experts, even upon opposite sides, they will usually give the same answer. Differences can honestly exist only upon unsettled questions, or on matters of pure theory, or upon inferences from partial and incomplete data. When, therefore, the question involves settled facts of science, or the status of newly advanced opinions, or the scope of new or old discoveries, the experts can and should be compelled to give the same answer. Suppose, for example, the question relates to the possibility of arsenic occurring as a normal constituent of the human body. Every competent physiologist, every competent pathologist, every competent toxicologist, every competent medical chemist knows the facts, and can by suitably framed questions be made to give a correct answer

—or to stand exposed as a pettifogger. Stated in a general way the facts are these: Gautier states that he has obtained by a certain series of chemical manipulations indications that very minute traces of arsenic are sometimes present in some form in normal tissues, especially the thyroid gland. Two or three other chemists have confirmed these observations; still other chemists have repeated the processes of Gautier and obtained contradictory results. The consensus of professional opinion is as yet against the correctness of Gautier's conclusion and in any event—even should it become demonstrated beyond doubt—it has no bearing upon a given case in which weighable quantities of arsenic have been recovered from the tissues other than the thyroid gland. To give this dubious contention an artificial and unwarranted importance may be legitimate tactics upon the part of counsel for a defendant; it is not exactly scientific treatment of a grave question by a medical expert.

It must be admitted, however, and this is a fact for which blame rests alike upon counsel and upon experts, that expert witnesses are frequently placed, either willingly or unwittingly in the position of advocates, and in their testimony magnify the importance of trivialities, evade direct answers to questions that will bring out opinions contrary to the contention of the counsel in behalf of whose client they are testifying, or seek to qualify their answers in such a way as to obscure the force of their admissions. Furthermore, the cross-examination of expert witnesses is often of such a nature, either from its acrimonious tone or from its wide range, as to excite passion, to consume time unnecessarily and to introduce a multitude of theories and possibilities having little or no relevancy to the facts in the case at issue. All this tends to obscure truth and to make it extremely difficult for even a jury whose members possess more than the average knowledge and intelligence to sift out the relevant from the irrelevant testimony; or to gain a clear conception of what are really the important points in the case; or even to understand what is the actual opinion advanced by any expert witness, or whether the criticism of such opinion has been weighty or captious.

I have often tried mentally to put myself in the position of a juror before whom a battle of counsel, with medical experts as their thundering artillery, has taken place. I confess that I have been compelled to conclude in many such cases that in the absence of my own professional knowledge I should be unable to form an opinion of any kind upon the matters in dispute, except, perhaps, that expert testimony was inexact, uncertain, purchasable, or otherwise untrustworthy. I should therefore, in a murder trial in which the cause of death as alleged by the Commonwealth was an important link in the chain of evidence be compelled to vote for the acquittal of the prisoner. I should, of course, be doing grave injustice to the majority—perhaps to all—of the expert witnesses on both sides; but I should be unable to discriminate. My verdict might be right or wrong, but I would be in such a state of doubt that I could not under my oath and the instructions of the court, convict. Such a trial, therefore, is not fair and impartial, but gives an undue advantage to the prisoner. This may in the long run inure to the benefit of society. As to this, I have here no view to express. It does not, however, make for the discovery of truth or the repression of crime.

On the other hand, cases cannot only be imagined, but have actually occurred, in which an innocent person may be in danger of conviction for homicide, because of the difficulty of making clear to a jury the scientific principle upon which the defense rests. Indeed, I have been associated in such a case, in which it is true the testimony was appreciated by the judge, and as a result of his clear charge, a verdict of acquittal was rendered; but I have always been in doubt as to whether the prosecuting attorney realized the force of the scientific

evidence prior to the judge's exposition of it. At all events I could not reconcile his argument with such understanding on his part.

The safeguards that English and American practice throw around a person accused of crime, in counterdistinction to the Continental methods which seem to assume his guilt and to call upon him to prove his innocence affirmatively, ought not to be weakened. Rather should they be strengthened, as by condemnation of the atrocious and un-English, un-American, unjust, unmanly "sweatbox" system of police inquisition. Nevertheless, it should be perfectly possible to devise a system of judicial inquiry into the cause of death which shall be subject only to those drawbacks inherent in the obscurity of the subject—a method of trial that shall at least be free from the worst of those hindrances and possibilities of error and of miscarriage of justice which this mere recital of the wellknown facts of our present procedure in such cases has made evident. The more certain acquittal of the innocent, as well as the surer conviction of the guilty, demands some attempt at such method.

Any proposition to introduce changes or innovations in judicial procedure ought to be received with distrust and suspicion. It should be severely criticised and made to prove its worth and its justice. I, therefore, expect and welcome the most searching criticism of the propositions to be made in this paper. To save time, I shall omit references to literature or to forms of practice now in vogue either in this country or abroad; but I make no claim to originality. Whether my proposals have been anticipated or not, is beside the question. The question is whether they are worth considering. Moreover, they are tentative in form and suggestive in purpose; hence stated in outline only and not elaborated. Even if received favorably by this society, that would be but a very slight step toward their incorporation into the law of the State or the practice of the courts. Nevertheless, it is useless to point out defects unless we can at least suggest a remedy. Without especial reference to any particular method in vogue in Pennsylvania or elsewhere, now or formerly, we may, perhaps, by taking up the subject *de novo* be able to see what are the necessary requirements of an orderly procedure, and thus to indicate the lines along which modification of present methods should proceed—even if we cannot immediately arrive at a method entirely free from criticism.

Let us consider (1) what are the points necessary to be brought out in order to determine the cause of a given death; (2) what are the tests of accuracy to be applied to evidence upon these matters; (3) in what manner should this evidence be presented; and, finally, (4) what are the qualifications for judgment upon it?

1. *Points Necessary to be Brought Out.*—The problem of the cause of death in a given case is, in the first instance, purely scientific. It has nothing to do with the presence or absence of felony in the case; nor, in a case with which felony may be associated, with the motive of the criminal. Its relation to these begins only after it has been decided. Obviously, an examination in which several unrelated subjects are inquired into at the same time, and a decision reached upon all combined, is entirely unsatisfactory from a scientific viewpoint, both as to method of inquiry, and as to form of decision. Yet such is our present practice. The first proposition then, that I would make, is that in a murder trial, the question of the cause of death should, when possible—and I find it difficult to imagine cases in which this would not be possible—be determined apart from, and in advance of, the question of the guilt or innocence of any individual. Such determination would thus be removed from the atmosphere of passion that must attend the trial of an individual; and also be undisturbed by the extraneous testimony that must, at the least, interfere with the logical presentation of the testimony bearing upon the question to be decided.

What then are the facts upon which a decision as to the cause of death in a given instance can be based, and as to which testimony should be restricted in an inquiry of the nature proposed? They are:

1. Relevant circumstances preceding and attending the death; including, but not confined to, the symptoms, if any, manifested by the person whose death is under investigation, and the results of any special examination made during life.

2. The manner of death.

3. The results of postmortem examination; including therein microscopic studies, and in certain cases bacteriologic and chemical studies of portions of tissue, of secretions or of other materials taken from the body, or of cultures made from the blood or tissues, and in some cases, tests upon animals. In cases in which certain relevant facts can be shown, for instance, that a certain substance was administered, or a certain weapon used, or that certain stains were found upon the body or upon the clothing, the results of tests bearing upon these facts, *i. e.*, as to the nature of the substance, the character of the stains, the sort of wound the weapon would be likely to make, etc., would likewise be admissible.

Upon naked eye postmortem appearance alone, a diagnosis of the cause of death is impossible in many cases; hence the necessity in such cases for microscopic and bacteriologic studies, if only to exclude certain of the possibilities that may be suggested by the circumstances of a given case; but even upon thorough postmortem studies of the tissues, including bacteriologic research, the cause of death may not yet be apparent, and hence the necessity for chemical studies to detect poisons of any kind, whether formed within the body or introduced from without. But chemical evidence alone does not indicate the cause of death. Pathologic evidence—that is to say, tissue changes, apparent to the eye, or revealed by the microscope, must also be present in the case of agents known to produce such changes. Conversely, tissue changes must be absent or explainable in the case of agents known not to produce them. Moreover, even should chemical studies, bacteriologic studies, and tissue studies all be thoroughly made and tend to the supposition that death has occurred from the administration of a certain poison, this conclusion cannot be said to be beyond doubt in every case, unless the symptoms observed during life or the circumstances attending death have also been such as are known to result from the administration of the poison in question. The same remarks, modified according to the special circumstances, apply to cases of death from violence—in which I include, of course, both accidental violence and intentional violence—and to deaths from those causes which physicians denominate "disease," and which, in the language of the law, are termed "natural causes." To warrant a positive opinion, there must be a concurrence of evidence, relating the symptoms shown during life, the manner of death and the results of investigation after death, with one and the same cause of death; and some portion of this evidence must be sufficient to exclude any other cause. It may be pointed out here, in passing, that evidence of the presence of disease does not necessarily exclude death from accident or felony. A man with kidney disease or with heart disease may be stabbed to death, or a child with tuberculosis or scarlet fever, may be poisoned. Moreover, even the evidence of death from disease will not exclude felony. I do not refer to miscarriage of felonious attempts, but to the fact that modern science offers to criminal ingenuity, a new method of assassination—which has indeed already been treated of in certain works of fiction.

In some cases positive conclusions as to the cause of death are impossible. The evidence of symptoms during life and of the manner of death are wanting or indefinite, or other data are insufficient. Depending upon the nature of the case and the nature of the avail-

able evidence, the cause of death may thus be subject only to a more or less probable determination, to reach which, other than scientific questions may have to be taken into consideration. For example, a stranger is found dead in bed in a room tightly closed and filled with illuminating gas from an open and unlighted burner. Without postmortem investigation and without any history of symptoms, the apparent conclusion is that the cause of death has been the inhalation of illuminating gas, and this may be true. Yet it might be possible that a murder has been committed and an attempt made to conceal the evidence of it in this manner. A sufficient postmortem investigation, then, might reveal evidence pointing to death by some other form of poisoning or to death by violence, and this might or might not be attended by such pathologic alterations in the body as might be consistent with exposure to the fumes of illuminating gas before death. In such an extreme instance as this, a judicial determination in the manner to be suggested might arrive at either a definite or a probable conclusion that death was caused—let us say—by the action of morphin or of a pistol bullet, or by the combined action of one of these and of illuminating gas; and the question of suicide or murder, which would thus be raised, might have to be determined not only from the scientific evidence, but also with the help of evidence of a different order. But one thing is very clear, whether in a case like this or in any other case in which felonious death is suspected, or in a case in which the liability of an insurance company depends upon the exact cause of death, namely, that thorough and sufficient postmortem investigation and not mere section and perfunctory examination of the body by the naked eye, may be a prime necessity. Whatever tribunal is called upon to make the decision, and in whatever manner the evidence may be presented and tested, that evidence should be as complete and as free from flaw as possible.

The greatest obstacle under present conditions to the presentment of this complete and flawless evidence is the existence of the office of coroner—and this need not arise from any fault or dereliction of any individual incumbent of this office; but from the nature and traditions of the office itself, is inevitable under the best possible administration. That the office of coroner once served a useful purpose, and was necessary and adequate to its purpose, may freely be admitted. That now it is a worse than useless survival is equally certain. For one thing, the public "coroner's inquest," with its summoning of witnesses and taking of testimony *pro* and *con*, not only as to the cause of death, but as to the possible guilt of any individual or as to the possible motives for felony or suicide, is open to all the objections that apply to such a method for the final trial in court; and without the excuses that apply to such a trial, where the liberty, or perhaps the life of some person accused, is in jeopardy and must therefore be surrounded by constitutional safeguards. Furthermore, the scientific examination which as we have seen, ought to be thorough and sufficient, is often unavoidably hurried or scantied or made in a manner open to attack, because of the supposed necessity to be ready with certain parts of the evidence before the coroner. It is quite possible, too, that a scientific study made under the direction of the public prosecutor would be made with greater attention to the necessities of judicial evidence in that special instance than is possible otherwise. For example, if a stomach supposed to contain poison is given to a chemist for examination, it should be opened by the chemist in the presence of the coroner's physician, or medical examiner, or other expert pathologist, in order that a competent examination be made of its condition from the viewpoint of pathology. Similar competent inspection should be made of all tissues before the chemist is permitted to destroy them in his tests. Chemists are not necessarily good pathologists, very often they are not physicians. Sometimes they do not even observe the gross appear-

ances of the viscera handled by them for purposes of chemical analysis, and in this way important links in the testimony as to the cause of death are lost beyond recovery; a circumstance that may be hurtful to the defense in some cases, or may hinder the prosecution in others. In any event, facts necessary to a true understanding of the case may be lost. A prosecuting officer, experienced or well advised, would provide for a conjoint examination that would preserve such facts. Without going further into this phase of the subject, the Massachusetts practice of preliminary investigation by an official medical examiner may be suggested as offering a basis for a practicable and satisfactory substitute for the coroner's inquest; or the preliminary inquiry before a commission of experts, suggested later in this paper, may be utilized for the purpose.

2. *What are the tests of accuracy to be applied to the evidence submitted upon the heads just discussed?* This is perhaps the most important portion of our inquiry.

In a case of suspected murder, the results of the examination of the body and other substances, and the verbal accounts of those who have observed the death and its attendant circumstances are usually presented as portions of the evidence for the prosecution. The examination, moreover, is in the hands of state officials, or of special experts appointed by the public prosecutor. In view of the known fallibility of all men, it is not to be expected that an accused person should accept without question the findings thus obtained. But how shall these findings be challenged? The method of unrestricted cross-examination and production of expert opinion in contradiction with further cross-examination and possibly rebuttal and surrebuttal, has been weighed and found wanting. It tends neither to the discovery of truth, to the establishment of justice, nor to the good repute of the professions of medicine and chemistry—to say nothing of the science of law. Is there any substitute? Several are possible, all, it is true, open to objection. Let us, however, pass some of them in review, and perhaps we shall find them less objectionable than present methods, and to that extent, an improvement. The object is to guard the rights of the defendant while not hampering unduly the preparation of the Commonwealth's case.

A. *Examinations may be made conjointly* by experts for the State and experts for the defense. The details of such a plan while attended with some difficulties, could be satisfactorily arranged in most cases. The 2 experts at work upon a given investigation should be required either to agree upon the findings at each step, or to record their differences; a third expert previously agreed upon by both sides, to be called in when any such difference occurred, whose finding would also be recorded.

This, of course, presumes that there is a specific defendant. Now the prosecution may not be in position to accuse a definite individual until its examinations are completed; while it would be suicidal for anyone to volunteer to play the part of defendant in advance. Still there are cases in which such conjoint examination is possible either in a first study or in a supplemental study, and it deserves to be put to the test of practicality in every such instance.

A'. In the *absence of a specific defendant* the court can constitute itself representative of all possible defendants and appoint an expert to be associated, on behalf of the court, with the expert for the prosecution. This is a method also deserving to be tested sufficiently to determine its value.

Neither of these methods (A and A') involves any decided change in existing law. It is my impression, though I speak subject to correction, that the matter is, under existing law, wholly within the discretion of courts or prosecutors.

B. In the *absence of conjoint examinations* the experts for the prosecution can be required to make complete investigations with a portion of their materials only,

and to reserve, at each critical stage, a sufficient portion to allow the tests to be repeated by experts for the defendant whenever some one shall have been made defendant. This is possible in many cases, and with many tests; not in all cases or with all tests. But when and where applicable, the practice should be made obligatory. Here it is only fair to say that the question of skill comes in; for it might be possible for the defense to get honestly negative results by selecting an unskilful person as expert. It might be necessary therefore to have a State's expert himself repeat the manipulations in the presence of the representative of the defense. This of course is merely a matter of detail. The principle of conjoint or supervised examination I consider of great importance. The 3 methods suggested are not mutually exclusive but mutually supplemental.

C. Experts, whether for the prosecution or for the defense should be required to *preserve and to present in court* the important material results of their investigations, be these positive or negative. The organs and tissues said to be inflamed, or to be normal; the bacterial cultures, the chemical precipitates, the microscopic slides, said to be demonstrative of the presence or absence of disease, injury, or poison, should, whenever possible—and to some degree at least this is possible in the vast majority of cases—be exhibited and offered for scientific criticism. Such exhibition, in the absence of conjoint or supervised examinations as previously suggested, should be accorded to the defense in advance of trial, in order that its experts may be qualified to pass truthful and intelligent opinions. The exhibition of negative results and the revelation to the defense of the results of the prosecution's examinations may be objected to as depriving the State of a tactical advantage. Such objection might be worth considering in an academic debate or a game of chess, but scarcely when the object is not the winning of a contest, but the discovery of truth; when the stake is not reputation, prize or title, but a human life.

D. The tests previously suggested refer to objective results, and also in part to methods; for methods can be criticised both in conjoint examinations, and upon exhibition of results with narration of methods. There is another factor, however, to be considered, and that is the *knowledge, competency and skill of experts*. This is a matter offering extreme difficulties. When oral testimony before an ordinary jury is giving, the most competent man may make, from the attorney's viewpoint, the worst witness. He knows his subject, its doubts, its difficulties; and whether he testify for prosecution or for defense, his direct testimony is conservative and limited to facts and opinions that he can maintain before a learned society. His answers upon cross-examination are frank and direct. The unqualified witness knows so little that he is dogmatic and positive upon matters not admitting either of dogmatism or positiveness, and hence he often makes a stronger impression upon the jury than does his competent opponent or colleague—while the great or little knowledge of the unscrupulous man affects his testimony as little as do the facts in the case, or the principles of science.

The years of study, or experience, or the number or importance of the official positions or titles of the expert witness amount to little as a test of qualification. Men who have achieved eminence sometimes let science outstrip them; responsible positions are sometimes held by men who are careless in work or reckless in statement. On the other hand, many careful and accurate workers are young men known only to their colleagues; or older men who have failed to receive the professional distinction that is their due. To attack the competency of witnesses would be as futile as ungracious. There is but one way to discriminate between the competent men forming the great majority of those who are placed upon the stand as medical expert witnesses,

and the very small minority of ignorant, inaccurate or untruthful men who may occupy a similar relation to a trial; and that is to have their testimony judged by an expert jury.

3. *How shall the evidence be presented?*

4. *By whom shall it be judged?*

The answer to these queries has just been suggested. The only persons competent to pass upon the qualifications of expert witnesses, are likewise the only persons competent to judge the relevancy and weight of the medical evidence, expert or ordinary, and to draw correct conclusions therefrom.

A jury (or commission) of experts, not necessarily 12 in number—better, probably, 5 or 7—to be constituted in a manner to be agreed upon, should be empaneled, to try the cause of death, and that issue only. To this jury the evidence should be submitted in open court, with presiding judge, with counsel for defense, with public prosecutor, as now in the ordinary trial. There should be every opportunity given for relevant cross-examination, and for the production of relevant testimony by the defense, as well as by the prosecution. No mere opinions should, however, be submitted as evidence; only the facts and the exhibits—with such opinions as might be necessary to bring out the bearing of the facts and the exhibits. If the methods of conjoint or supervised examination previously suggested have been adopted, the evidence would be simpler and more conclusive. Experts frankly appearing in the capacity of advocates, could assist counsel upon each side in examining witnesses, and in arguing to the jury. In such arguments would be the proper place for the expressions of opinion, and the opinions thus expressed would not only be clearer than those given by experts testifying in the customary manner, but they would be judged by a more competent tribunal. It is probable that counsel might be content to leave the argument entirely to the medical advocates. This is a question that experience only could settle.

Before such a jury as has been suggested, no irrelevant testimony, no captious criticism, no extravagant statements, no reckless assertions, no badgering of witnesses, no dragging out of cases, no attempts at confusion of witness or jury, no placing of words not uttered into witnesses' mouths—in short none of the tricks of pettifoggers, none of the blunders of mistaken zeal would avail, and before long all attempts at such methods would be abandoned. The truth would be brought out, or it would become manifest that the truth could not be reached. Those charged with the duty of making examinations would be extremely careful about their methods, knowing that they would be called upon to defend these before a body of competent and unbiased critics. The court would see that only legal evidence was introduced.

As to the composition of such a jury or commission of experts, it would vary with the nature of the case to be tried. Should poison be alleged as the cause of death, physicians, chemists, and pathologists would be required. Should violence be the theory, surgeons would be substituted for the chemists. They could be chosen by the court, or appointed from lists agreed upon by the prosecution and the defense, or in any other manner deemed fair and practicable, and prescribed by law. The cost to the State, presuming that the members of the jury or commission were paid expert fees, would probably be much less in the long run, owing to the saving of time and the greater certainty of justice, than is the cost of trials as at the present conducted.

The jury, or commission, should not be required to reach a unanimous verdict, but a majority and minority report, or even several minority reports, or in an extreme case, as many reports as there are jurors, might be handed in. It is obvious, however, that only a unanimous report would have, or ought to have, conclusive weight with the petit jury, selected in the usual way, that

would then have to pass upon the guilt of the accused individual, and before whom the finding or findings of the expert jury would be merely an item or items in the evidence. The report or reports might assign a definite cause or causes of death; or state that the cause of death could be only probably assigned; or that it could not be determined at all from the evidence. In other words, instead of submitting to the petit jury having final decision in the case, the detailed scientific testimony and the opinions of opposing experts, there would be submitted to that jury authoritative and unbiased expert opinion, concurrent or discrepant, based upon the testimony. A concurrent opinion having been arrived at in open court, and by both scientific and legal methods, might well be presumed to be correct; but it would not be binding. Discrepant opinions—which are possible, but must in any event be rare—would bring into full relief all legitimate elements of difficulty or obscurity in the case; and while the jury would still have to pass upon them, the issue would be clear cut. The difference between reasonable and unreasonable doubts would be made apparent. It is conceivable that in certain cases the prosecution might be abandoned in consequence of the expert jury's report; but whatever effect or value it might have or lack, no right of the prosecution or of the defendant would be lost. Many opportunities for obscuring the issue would, however, be denied to both sides. Pettifogging would be discouraged. Truth would have a chance. Justice would be furthered.

SUMMARY.

The chief topics submitted for discussion are:

1. The necessity for thorough postmortem investigations.
2. The principle of conjoint or supervised investigation, and the 3 methods suggested for carrying it into effect.
3. The principle of material exhibits.
4. The principle of a jury or commission of experts to determine the cause of death apart from the question of the guilt of any accused person.

It is obvious that no one of these proposed remedies for present difficulties excludes any of the others; they are mutually supplemental. Should the proposition for an expert jury be rejected, the other propositions gain, rather than lose, in force and necessity. They could probably be introduced as a matter of practice, without alteration of statute law. In any event, they involve no constitutional departure. The principles accepted, with such modification of detail as might be necessary, could be applied to civil suits as well as to criminal trials.

OBSERVATIONS ON UNCINARIASIS.

BY

LOUIS M. WARFIELD, A.B., M.D.,

of Savannah, Ga.

It has been only recently that the attention of the medical profession has been called to the prevalence and wide distribution of human intestinal parasites in this country. Up to 3 years ago cases other than of tape-worm, pin-worm, and round-worm were classed as uncommon occurrences, and put on record in medical literature. The impetus given by our acquisition of tropical lands, and the untiring efforts of Stiles have materially changed our views as to the frequency of diseases due to intestinal worms. The more systematic examination of the stools of patients has also added much to our knowledge. The dissemination of parasitic diseases by troops returning from the tropics has been emphasized also by Ashford and Stiles at various times, and the profession has been urged to be on the watch for various tropical parasitic diseases. But that we had here in our midst a hot-bed of a grave form of parasitic infection was not imagined until Stiles reasoned from isolated widely scattered

cases that uncinariasis must be a condition endemic in our southern States. His trip through the South in 1902 amply justified his view, and, moreover, led to the discovery by him of a new species peculiar to our country, *Uncinaria americana*.

Cases reported from practically all the southern States show how widespread is this affection, and observations recently made by Smith and Harris, of Atlanta, Ga., show to what extent hookworm disease is a factor in the economics of the South. Whole communities are infected, and the consequent suffering and loss of the labor of infected individuals keep sections unproductive and have given rise only too justly to the opprobrium with which northern communities look on the southern "cracker."

The cause of this suffering being definitely settled, it becomes a vital question to find why so many individuals are infected, and what is the mode of infection. The eggs are deposited outside the body; they have to reach a certain stage of development into free embryos before they can infect man, hence it becomes necessary to find out how the worms enter the human intestine. The startling view advanced by Loos (1901) that worms reach the intestine after infection of the skin, has certainly seemed to receive confirmation from his experiments. Bentley (1902) succeeded in finding in water-sores on the feet, larvae which he identified as those of *Ankylostoma duodenale*. He does not accept the view of Loos, however, as to infection through the skin. Recently Smith accepted this view of Loos and urged the frequency of antecedent ground-itch in support of his view. He laid comparatively little stress on infection through the mouth. It is well known that the ground-itch season coincides with the period of greatest prevalence of uncinaria larvae. Warm wet weather is the condition most favorable to both. No ground-itch occurs in dry weather, and only children who play barefoot around puddles contract the disease. It is also a popular idea, borne out by the experience of many generations, that ground-itch is contracted even in dry weather if one plays barefoot in grass wet with the dew. All slight lesions on the foot seem to predispose to the infection. One attack of the disease confers no immunity. On the contrary, it appears to favor a second attack. While large numbers of children, both of the better and lower classes, go barefoot throughout the entire summer in the South, not all have ground-itch, although playing side by side. That uncinaria eggs are found in the stools of children who have never had ground-itch shows that they must have been infected from without, or by the hands of the individual.

Anemia with a sallow, washed-out, muddy parchment complexion, is one of the most prevalent conditions throughout the country districts of the South. These cases were always thought to be a consequence of malaria, and it is only quite recently that Harris threw doubt on this long-held idea, by stating that in his opinion these cases were due to uncinaria, and not to malaria. Such a malarial hypothesis has existed for years in this locality, the expression, "a touch of malaria," being used to cover the ignorance of the true condition.

Having examined the blood and stools of a number of patients, the subject of anemia, and finding in all cases uncinaria eggs, and in no case malarial parasites, except when the history and temperature left no doubt that one was dealing with malaria even before the organisms were found in the blood, it was determined to make an investigation in this locality.

Through the kindness of Mr. Chaplin, I was able to examine a number of boys at an orphan asylum about 7 miles from Savannah.¹

¹ This asylum, The Bethesda Home for Boys, is situated on a bluff on the mainland, about 12 feet above high-water mark. The salt marshes bound one side, and a small salt-water creek comes up to the bluff, which at low tide contains no water. In this creek at high tide

It proved rather a difficult task, as the boys are constantly at work in the fields, and occasionally are off in the woods. However, 60 of the 100 boys were examined, the ages varying from 6 to 16 years. As these were not selected cases it is safe to conclude that the results of these examinations may be applied to the whole school. More than half were born in or around Savannah. The others came from Montgomery, Ala.; Atlanta, Effingham Co., Brunswick, Milledgeville, Liberty City, Bulloch Co., and Tarville, Ga. Still others were born in New York, Philadelphia, Baltimore, 1 in Denmark, and 1 in Germany, the last 2 had been in this locality for 5 or more years. All these born in the North had lived in Georgia for several years. The boys, with very few exceptions, go barefoot from April until cool weather, usually October. A glance at the inmates shows an apparently sturdy, sunburned crowd of boys, but close inspection reveals the fact that very many have sallow, muddy complexions, while some show marked grades of anemia. Although many of the boys were evidently somewhat under size, there was no dwarfism with the "potbelly" so characteristic of the very severe grades of infection with uncinaria. The eye-symptoms described by Stiles were not seen in a single case, although looked for carefully. Possibly the infections were not sufficiently severe. As almost all the boys were below the age of puberty, no opportunity was furnished of seeing the effect of the anemia on the sexual development. There can be no doubt, however, that were the boys to grow up untreated, many would show lack of physical and sexual growth. What was noticed in many cases was a curious lack of expression, amounting in some cases almost to a mask, which seemed to be drawn over the features, giving the patients a very stupid appearance. The pupils were dilated in some cases, normal in others. No uniformity was noticed. In 1 case in a freshly passed stool, a free embryo was found along with numerous uncinaria eggs in all stages of segmentation. Probably this was an embryo of uncinaria, and not of *Strongylus intestinalis*. Although it is very rare to find a free embryo of uncinaria in freshly passed feces, it nevertheless occurs occasionally.

Forty-eight or 80% of the boys were infected. All grades were found except the very severe type. In some it was very difficult to find one egg after looking over 10 slides; in others, the first slide showed 2 to 6 eggs. The size of the eggs corresponded to the size of those of *Uncinaria americana*. No adult worms were obtained. In one case, eggs of *Ascaris lumbricoides* were found, in 2 cases, eggs of *Trichuris trichiura*. Twenty-three boys were under 10 years, 37 between 10 and 16 years. The youngest positive case was in a boy of 7. As said before all the boys who harbored uncinaria were the subjects of more or less anemia. Twelve boys gave a history of having had 1, or at most 3 attacks of chills and fever. Five gave an indefinite and doubtful history of previous malaria. All had been treated with quinin and had recovered completely.

The healthy out-of-door life the boys are obliged to lead should make them strong and anything but anemic. The fact that they are anemic, tired, and show lack of application in study can be due to only one cause, uncinaria infection. Malaria is out of the question. Two boys during the past summer had short attacks of malaria.

So much stress of late has been given to the question of ground-itch in relation to uncinariasis that this was especially noted in the cases. The results are exceedingly interesting. Forty-five of the 48 positive cases gave a

the boys bathe. In the Home, which is one large building, are about 100 boys, who sleep in dormitories and are much crowded for room. The drinking water is of the best, from artesian wells sunk 100 to 200 feet below the surface. The water is conducted up to the surface by pipes, and is flowing constantly. On the grounds are 4 open privies, each one having about 6 seats. An investigation showed numerous traces of barnyard fowls behind the boxes. These boxes were easily accessible to the fowls, and no doubt the infection is kept alive by dissemination of material by means of the fowls, as the boys invariably make use of the privies to defecate.

history of 1 or more attacks of ground-itch. In 3 positive cases the patients were sure that they had never had ground-itch. In 2 negative cases the patients had had the disease and in 10 negative cases they had never had it. Two of the 10 patients mentioned, said they always wore shoes as they did not want to get ground-itch. The 3 positive cases mentioned were as follow:

CASE L.—The patient, 13 years old, had been at Bethesda 7 years. No ground-itch. Went barefoot all summer.

CASE XXIX.—Patient, 7 years old had been at Bethesda 1 year. No ground-itch. Always went barefoot.

CASE I.—The patient, 9 years old, had been at Bethesda 3 years. No ground-itch. Went barefoot all summer.

This agrees with my personal experience that not all exposed to the same conditions contract the disease.

Smith states that the number of eggs to the stool is in proportion to the severity and number of attacks of ground-itch. This was not the case in the series presented. In the case which showed the greatest number of eggs there had been only one moderately severe attack of ground-itch, while in several cases in which there had been repeated and fairly severe attacks, eggs were found only after long and careful search. That the embryos can reach the intestines by any other route than through the mouth seems scarcely credible. The possibility cannot be absolutely denied, since so accurate an observer as Loos is authority for the statement. Yet it would seem strange that an organism 0.65 mm. to 0.7 mm. in length by 25 microns to 27 microns in breadth should be able to travel either by way of the lymph-channels or bloodvessels, and pick out the small intestine, through the wall of which it would have to bore. We know that dogs can be readily infected by feeding them with larvae, and it would appear more likely that man is infected in a similar manner. Loos' experiments, in which he rubbed larvae on the backs of puppies and after killing them found worms in the intestines, are remarkable to say the least. Further experiments eliminating all possible chance of infection through the mouth seem necessary before one can accept this idea.

That ground-itch and uncinariasis are related, in that one predisposes to the other is, in my opinion, beyond doubt. The mode of infection I believe is as follows: Children are not any too cleanly about their person. Nails are long, full of dirt, and the hands are carried to the mouth constantly. Ground-itch well deserves its name as there is probably no skin disease in which the patient feels more like tearing his flesh out than this. The itching is constant but worse at night. Children literally do tear their flesh, breaking the vesicles, and scratching the raw flesh. I believe that the embryos get on the fingers, beneath the nails, and in that way are carried to the mouth. The habit, too, of drinking water in the hollows of the hands is an easily conceivable mode of infection. The children in such cases infect the water with their hands. Finally, some certainly are infected by drinking water containing embryos that have been washed in from the soil, as is shown by the 3 patients, who, although having eggs in the stools yet never had ground-itch.

So certain am I that ground-itch in children is the precursor of uncinariasis, that in cases of anemia with an antecedent history of ground-itch I always expect to find, and almost invariably do find, eggs in the stools. I fully agree with Harris that the vast majority of anemias through the South are due, not to malaria, but to uncinariasis, and I feel that the more men make routine stool and blood examinations in cases of anemia, the greater will be the number who come to a similar conclusion. It is uncinariasis that is sapping the life-blood in the country districts and the sooner this is realized the better. It is a burning economic question with us, for as Smith remarks, those who now can only do a portion of a day's work in an indolent fashion will be able to do a full hard day's work with a consequent increase in the productiveness of the family.

The prophylaxis of uncinariasis is unquestionably a difficult problem in consequence of the wide distribution of the disease, and the extreme aversion that country people have to any outside interference. I doubt if any class of people are more suspicious than the average "cracker." An amelioration of the condition could be brought about in a short time by building proper latrines as urged by Stiles, and seeing that children use them. As the embryos of uncinaria do not survive frosty weather such a measure would, in the course of a short time, certainly better the condition. The problem is one for the country doctor, the man who above all has the confidence of the community. Outside interference almost invariably meets dogged opposition, so it is to the country professional man that we must look to educate the people to the full realization of their lamentable condition. No sane man could long entertain the idea that the children should be made to wear shoes and stockings and be made cleanly. Such propositions would defeat at the outset all our good intentions and make our best efforts of no avail. State Boards of Health and legislative measures in general would be productive of more harm than good. The inevitable conclusion is forced upon us that we must first educate the profession in the country districts to the realization of the role played by uncinarias and beg for their hearty and untiring support in this problem. No need, really, to examine stools in the country in cases of anemia when we know now that the uncinarias are causing the anemia. Thymol and castor-oil for the individuals, and education for the masses, are what are imperatively needed. Briefly to summarize, it is believed that uncinariasis is one of the commonest diseases in the South. It is the chief cause of anemia in children especially, as they are the ones most liable to infection. Adults, if not too badly infected, seem to outgrow it, presumably through death of the worms. Ground-itch is intimately associated with uncinariasis, and infection most probably arises from contamination of the hands and later swallowing the embryos. Infection other than through the mouth is thought to be very improbable. While no adult worms were found in the cases mentioned herein, the size of the eggs left no doubt that the infecting agent was *U. americana*. Prophylaxis rests with the country physicians who should urge the building of latrines or privies that can be easily cleaned and disinfected, and which are closed below, so that barnyard fowls cannot get at the discharges, and so protected that rain cannot wash the discharges over the adjacent soil. Parents should then see that children use the privies, and do not defecate wherever they happen to be when they feel the desire. As it has repeatedly been shown to be impossible to infect man with the uncinarias of dogs or of other animals, the problem of prophylaxis is simpler than it would otherwise be. Here man is his own worst enemy.

To an optimistic mind a glowing future can be pictured for the southern country communities so soon as we are able to control the worst foe of labor that we have. Once we rid our communities of this vampire, this blood-sucker, a new era will dawn for the southern country districts.

NOTE.—Since writing the foregoing, I have had opportunity to examine a number of cases of anemia in young adults who have come from the surrounding country districts. In all cases which gave an antecedent history of ground-itch, eggs were found in the stools. In 1 case worms without doubt have lived in the intestine for at least 13 years. The patient, now aged 22, had not lived in the country since she was a child. She had had at that period several attacks of ground-itch. So far as could be learned, the chances of infection since childhood are infinitesimal. Stiles' longest case was 6 years and 7 months. With such longlived parasites, it behooves all sections of the country to be on the watch when patients from the South with anemia present them-

selves for treatment. Careful inquiry as to ground-itch will, in such cases, put one on the right track.

RESULTS OF AN EXPERIMENTAL TREATMENT OF EPILEPTIC INSANITY.

BY

J. W. WHERRY, M.D.,
 of Clarinda, Iowa.

Assistant Physician, Clarinda State Hospital.

When the average human mind surveys the various and diversified conditions assigned as causes of epilepsy, it is in great doubt whether or not to regard them as the product of serious consideration; for the enumeration includes almost every disability to which human flesh is heir, and every anatomic lesion which the most active mind can conceive, or the wildest imagination suggest; and if we have advanced so little that we cannot, as yet, expunge, with safety, the earliest and most trivial conceptions of the disease, then do we indeed occupy a most unpromising situation.

In a textbook recently issued the following conditions, 75 in number, were given as causes of epilepsy:

Heredity,	Pregnancy,
Application of forceps,	Puerperium,
Lying always on the same side,	Alcoholism,
Wearing a close-fitting cap,	Plumbism,
Defective hygiene,	Chloroform,
Alcoholism of nurse,	Ether,
Traumatism,	Morphin,
Menopause,	Opium,
Menstrual disturbances,	Tobacco,
Imperforate hymen,	Cocain,
Ergot,	Scarlatina,
Uremia,	Typhoid fever,
Syphilis,	Neuromas,
Dentition,	Toothache,
Worms in the nares,	Irritation of epileptogenic zones,
Foreign bodies in frontal sinus,	Impaired nasal respiration,
Irritation of auditory nerve,	Inflammation of eustachian tube,
Chronic otitis,	Eruption of wisdom tooth,
Errors of refraction,	Laryngitis,
Pleuritis,	Pleurotomy,
Indigestion,	Enteritis,
Worms in the intestines,	Tapeworm,
Hepatic colic,	Orchitis,
Uterine disease,	Cerebral tumors,
Intracranial effusion of blood,	Compression of spinal cord,
Fistula,	Shock,
Grief,	Fear,
Prolonged anxiety,	Sexual excitement,
Cholera,	Pneumonia,
Meningitis,	Renal lithiasis,
Stricture of urethra,	Excessive length of prepuce,
Ménière's disease,	Encephalitis,
General paralysis,	Lesions of cortical motor zone,
Lesions of frontal lobe,	Lesion of parietooccipital lobe,
Lesion of sphenoidal lobe,	Lesion of pyramidal tract,
Irritation of medulla,	Irritation of cortex,
Anemia of brain,	Hyperemia of brain,
	Autointoxication.

All of which would indicate that we either have an unusually clear and comprehensive knowledge of the disease, or that we know nothing whatever about it. The latter view would be gloomy indeed, and admitting the meagerness of positive knowledge, I, for one, am disposed to be more optimistic than this.

It is useless to contend that the foregoing are all causes of epilepsy, for the list itself is ample evidence of the fact that in seeking for the cause, each man found just what he was looking for, and no more. It is true that each of these may affect, more or less, the epileptic condition, and possibly, seriously aggravate it, but this is incidental, not causative. Certain physical conditions may precipitate an attack of pulmonary tuberculosis, but the real cause of that disease is too well known to

permit of any errors regarding its etiology. To accept the list quoted as actual causes of epilepsy is to paralyze research, for it would be a waste of time to seek for another progenitor of a disease already provided with such a diversified and numerous parentage. It would be much better to stimulate research by admitting freely, however disagreeable it may be, that the cause of epilepsy is absolutely unknown, and that the whole field is open and courting investigation, for in the face of all this vast array of assumed causes, it is very doubtful if any one seriously believes that the real cause of epilepsy has yet been definitely named, and the following remarks regarding a new method of treating epilepsy are not offered as a demonstration of another cause, or as a solution of the whole problem, but merely with the hope that it may be of some service in solving the first equation, by endeavoring to establish some relationship between the known effects of this disease and an unknown cause—this connection, if any exists, being formulated as a physiologic condition, namely, a vasomotor spasm.

In State hospitals for insane, epileptics form a class by themselves. They are unique in many ways, and stand solitary and alone, having nothing in common with other patients so far as care and treatment are concerned. Ever since their first admission into these hospitals they have been the source of the greatest anxiety and concern, and questions regarding their management and control have ever called for the gravest consideration. They are the most disagreeable patients in the institution. They are irritable, quarrelsome, violent, and vicious, and disorderly in every conceivable manner. Many of them, either preceding or subsequent to the convulsion, become dangerously violent and make most vicious attacks upon friend and foe alike, regardless of the consequences to others or to themselves. Two-thirds of the troubles occurring in the institution have their origin in the epileptic ward, and their influence on other patients is uniformly harmful, not because of the convulsion alone, but because of the dangerous and disagreeable qualities enumerated, and which seem to be characteristic of the great majority of the epileptic insane.

For years their segregation has been recommended, and superintendents of State hospitals for insane have ever stood ready to welcome any proposition which provided for their removal from these institutions. Their recovery was practically hopeless, their improvement doubtful, and their presence inimical to the best interests of the hospital. This was the situation at the Clarinda State Hospital in July, 1901, when after due consideration, it was decided to adopt some form of treatment which might give hope of relief. There was no expectation of curing epilepsy, nor of even controlling the convulsion; in fact, the convulsion was eliminated from all consideration. The chief object and desire was to alleviate the irritable and quarrelsome tendencies and, as a result, secure immunity in a measure from violence and disorderly conduct. We had tried the bromid treatment, and Flechsigs's treatment, and a period of rest without any special treatment, all without avail. While we were beating the brain into insensibility with the bromids, there was some abatement in the frequency and severity of the convulsions, but the irritability and disorderly conduct increased and the situation was worse than before. While the patients were stupefied with opium, there was some relief from the violent and vicious tendencies, but the limit was soon reached, the disagreeable features returned, and the treatment was abandoned.

The theory which holds that epilepsy is a condition of autointoxication, producing a vasomotor spasm, from which the convulsion follows, was thought to be worthy some small amount, at least, of investigation and experimentation, and it was decided to adopt a course of treatment directed toward the vasomotor system instead of toward the brain. It was to be a combination of drugs,

which would, if possible, prevent excessive vascular constriction and at the same time improve the general health. It was based upon the nitrites instead of upon the bromids, and its object was vasodilation rather than brain stupefaction.

The proper treatment of any disease is to launch the remedy straight at the cause; but in the absence of all knowledge of the cause, experimental measures must be employed. It was believed that the prime cause of epilepsy was a self-eliminated toxin, whose presence produced excessive constriction of the arterioles, and that the unconsciousness and the convulsion were the legitimate physiologic offspring of this unusual vascular spasm. If this were true, the prevention of this vasomotor spasm would afford the epileptic temporary relief, at least, until such a time as the identity of the prime cause could be discovered and attacked, and indeed, might throw some light upon this cause so long and so assiduously sought. Whether or not the remedies introduced would produce vasodilation under these peculiar circumstances, or, if produced, whether the vasodilation would have any effect on the epileptic condition, were matters to be determined only by experimentation. The asphyxial idea of epilepsy had, at this time, been scarcely born, or, if born, was still in swaddling clothes, and the results of this experiment had much to do with the formulation and publication of that theory.

This treatment was inaugurated in July, 1901, and is still in use. No real or assumed recoveries can be reported, and none was expected, but the object sought has been accomplished, and the improvement in conduct and in the patients' general, physical, and mental condition has been all that could be desired, and much more than was hoped for. These patients have not been transformed into "angels in disguise" by any means, but they have become quiet, orderly, more pleasant and agreeable, and their conduct, as a rule, is above reproach.

Those who have had the care of epileptics in hospitals for the insane will appreciate fully what this change means. They know what a disturbing element this class of patients has been, and can realize what a sense of relief would come from this calm and comparative degree of quiet, succeeding, as it did, the reign of disorder and confusion incident to the epileptic ward. Prior to July, 1901, 4 nurses were required on the epileptic ward under consideration, and it was deemed unsafe for it to be left, even temporarily, with a less number; at present, with the same number of patients and practically the same individuals, 2 nurses are all that are necessary; chairs, which previously could not have been used with safety, have taken the place of settees; muslin and lace curtains have been added; center-tables, flowers, and various pieces of bric-a-brac have been introduced, and instead of 1 or 2 daily calls, in addition to his regular rounds, for a physician to quell some disturbance, this ward is now less in evidence than others containing no epileptics. The quarrelsome and irritable disposition has practically been eliminated, and with its exclusion the violent, vicious, and disorderly tendencies have disappeared.

The change, indeed, has been so remarkable that I regret my inability to reduce it to a tabulated form, or to present it in a more graphic manner. To the epileptics themselves it has meant a condition of comparative comfort and a widening of their mental horizon; to the nurses it has meant the reduction of an environment filled with commotion, tumult, and confusion, to one of ordinary, routine ward duties, and to the management it has meant the removal of an almost constant source of worry and anxiety.

During this course of treatment no change was made in the diet of these patients, because of its being impracticable, nor in their daily habits, and whatever benefits were derived must have come from the treatment itself.

It is also gratifying to be able to say, in connection

with the good results enumerated, that, while this treatment was not directed toward the convulsion, the improvement in the frequency and severity of this symptom was so marked as to attract attention. I append tables illustrating this feature. The 7 patients selected for these tables were considered the most disorderly and intractable of all on the ward, and, at the same time, their epilepsy was of the longest standing and their attacks the most frequent and severe. The months of May, June, and July, 1901, are included, as an indication of the number of convulsions occurring prior to the beginning of treatment, which was instituted during the second week in July. These patients are all women.

Total for month...			74	85	110	85	53	54	51	21	17	26	26	15

In the first column is the patient's number taken from our statistical record, followed by the age and the duration of epilepsy. The duration of insanity in each case was from 3 to 20 years. Following the duration of epilepsy is the number of convulsions of each patient occurring during the month, and at the bottom of the column the total convulsions for the month. In August, 1902, two of these were transferred to the Cherokee

State Hospital with other patients belonging to that district.

Attention is called particularly to the steady decrease in the number of convulsions, extending over a period of 2 years, showing a reduction from an average of 40 convulsions per month for each patient in May, 1901, to an average of 3 convulsions per month for each patient in April, 1903.

The preceding table shows rather more graphically the variation in the number of convulsions from month to month.

The 3 tables following will give an idea of the distribution of convulsions throughout the month, and it will be observed, in the first table especially, that they occur with marked regularity, and there was no unusually large number on any one day. To give a table for each month during the 2 years would consume too much space and, consequently, I give but the first, the middle and the last months of the period for purposes of comparison. During the month of May, 1901, there were as many as 13 convulsions from these 7 patients in a single day, while in May, 1902, the highest number for a single day was 8, and in April, 1903, only 3, while there were 18 days in this month without any convulsions. One patient, No. 2,142, had 51 convulsions in May, 1901, only 9 in May, 1902, and in April, 1903, none.

It might be well to say in this connection that the improvement in the condition of the other epileptics on the same ward, 18 in number, was more marked if anything than that of those given in the tables. One patient, for instance, who had attacks only once or twice a month, has now had none for 6 months. Quoting these exceptional cases, however, might lead to erroneous conclusions, and for that reason only the most pronounced and confirmed epileptics were selected as illustrations.

This is the record and these are the facts, stated simply as they occurred, uncolored and unadorned. The decrease in the number of convulsions is plainly evident; the decrease in their severity cannot be made a matter of statistics, but it is quite marked, though not to the same extent in all cases as the reduction in number. The one great object sought and accomplished, however, cannot be reduced to figures, namely, the disappearance of the violent, vicious, and disorderly tendencies, and the improvement in general bodily comfort.

What the effect of this treatment would be on the mildly epileptic, or those not insane, I cannot say, for I have had no opportunities for making observations, but the results of its use here have been so satisfactory that I have been led to believe that its further employment may be of some slight service in the future solution of that great problem of epilepsy, even though it be but a solitary finger pointing the way.

I have given no formula for the reason that I am not sure that the drugs used by me have been the best to be had. The one basic principle of vasodilation, however, has been ever kept in view, though the combination of drugs has been changed several times, and, indeed, may undergo still further modification. Consequently, I believe, if the fundamental principles are retained, namely: A combination of vasodilating drugs with a saline cathartic and an alterative, the particular ingredients to be used in each case can be safely left to the judgment and discretion of the attending physician.

With reference to the theory of epilepsy which regards this disease as a condition resulting from vasomotor spasm, the foregoing results are significant. But, whether these results are regarded as supporting this theory or are explainable by means of some other hypothesis, this treatment has much to recommend it, and I believe its use will do much for the epileptic condition.

In the very nature of things no man can hope so to illuminate the darkness surrounding epilepsy as to

stand that disease in the foreground, solitary and alone, with every feature clear-cut and luminous and every lineament distinctly revealed. Epilepsy cannot be lifted bodily from its hiding place and held up for public inspection. Its solution will never spring fully grown and completely developed from the womb of knowledge, nor will it appear in its entirety through any sudden flash of intuition or unexpected process of revelation. It will come, when it does come, in the form of single and isolated facts, which must be correlated and laid in their respective places, awaiting the day when all the solitary facts will have been discovered, and recognized, and arranged in their proper positions; then the grand mosaic will take on definite form and figure, and epilepsy as an entity stand revealed. In the present status of our knowledge of this disease no fact, however isolated or disconnected it may seem, can be rejected without serious reflection, and this paper, recording the experimental treatment of epilepsy, based on the theory of autointoxication and its resulting vasomotor spasm, is offered as one of these facts, and nothing is asked for it but honest and thoughtful consideration.

CARE OF SPUTUM OF TUBERCULOUS PATIENTS.

BY

J. W. KIME, M.D.,

of Denver.

Superintendent Boulder Lodge Sanatorium for Tuberculosis, Fort Dodge, Iowa, etc.

The sputum of the tuberculous is the one source of danger and of contagion in the home or in the sanatorium, and too much cannot be said of the necessity of every precaution being taken that all sputa be immediately destroyed by fire. I do not believe that any attempt should be made to destroy the activity of the tubercle bacillus by means of antiseptic solutions; they are uncleanly, are inefficient, and are much more inconvenient in every way than the institution of measures for the destruction of the bacilli by fire. Tuberculous sputum should always be destroyed before it dries, not that it is more dangerous

when dry, but that proper cleanliness demands it. In fact, I do not believe that the dried bacilli are often a source of infection. They rapidly lose in virility on exposure to light and air, and I think too much has been said about the danger of dust as a carrier of contagion in this disease. This does not imply that less care should be taken in this direction, but it should be urged everywhere that the fresh sputum should be burned at once. There can be no question that the tubercle bacillus is most dangerous in its fresh, moist state when first expelled from its host. Were this not so, and were it true that the dried bacilli which blow about the streets or are wafted about the rooms of well-lighted houses still retained their power to do harm, none would escape the ravages of tuberculosis. That we do escape is due to the fact that but few active, virulent bacilli find lodgment in suitable soil for growth and development. It is in the sputum fresh from the lips of the tuberculous or that has lain in dark and unventilated rooms that the danger lies. Immediate destruction of the sputum and the free admission of fresh air and sunlight to every room reduce to a minimum the dangers from infection from this source.

In close, dark rooms, the tubercle bacillus undoubtedly retains its potency for an indefinite period, and in densely populated and crowded districts, as in tenement sections where there is but a very meager supply of sunlight and fresh air, this source of danger is very great.

When the public fully appreciates that tuberculosis is strictly a preventable disease, that every case is dependent upon some previously existing one either in man or in some domestic animal, and that it never originates in any other way, then we may obtain cooperation in the prevention of the spread of this fatal malady.

Popular education is necessary, and the first thing to be learned is that the bacilli must be promptly destroyed. If no bacilli fell under suitable conditions and in favorable places for their development, then the lifetime of a single generation would mark the extermination of tuberculosis, but if each individual now suffering from it is permitted to infect one or more healthy

persons, then there will be no progress made toward its suppression, but there may be an actual increase in the total number of cases.

The principal sources from which infective bacilli come, are two—milk from infected cows, and the sputum from tuberculous persons.

Compared with these sources of danger all others are of slight importance. Omitting for the present a consideration of bovine tuberculosis, attention will be briefly called to the dangers which lie in the sputum of the tuberculous patient.

There is today in this country alone, traveling up and down the various avenues of life, a vast army of tuberculous persons, more than a million and a half in number, hawking and spitting, each one spreading millions of living, virulent bacilli all about him, in his room, about his home, upon the streets, in public places, in railway and sleeping coaches, in street cars, cabs, and in every conceivable place where he may chance to wander.

So widespread is this disease and so numerous are its victims that almost daily contact with these germs must be had by every individual in the country; and these dangers are infinitely multiplied by the carelessness of the patients and the lack of general information on the part of the public concerning the proper care and disposition of the dangerous excreta from these persons. It is self-evident that not all who are exposed to the dangers of tuberculosis contract the disease, otherwise none would escape, yet it is just as true that no person is known to be immune to it.

The most important thing to be done against its spread is to educate all the tuberculous in the proper care of their sputa. To locate these persons it becomes practically necessary that they be registered, for if thus made known to their proper health authorities it would be possible to place in their hands the rules and regulations necessary for their guidance and direction and for the protection of those whose unfortunate duty it becomes to be associated with and to care for them as well as to safeguard the general public from the dangers of further spread of the malady. It is due in large measure to lack of proper understanding of the purposes of such registration that opposition, largely of a sentimental character has been set up against it, but as its true objects become better known, opposition ceases and the active cooperation of the patients themselves is obtained. No publicity should be attempted in registration and the health authorities alone should be acquainted with the facts. While this educational movement is taking place much good may be done by physicians calling attention of such patients to the necessity of proper precautions to be taken for the protection of their associates and friends. The average tuberculous person expectorates many millions of bacilli each day and frequently these are spat upon the floor or upon the grounds about the house where they may find entrance into the air passages or digestive tracts of others and thus the primary focus of infection is extended until all the members of the family, together with its descendants, may be afflicted with tuberculosis. Hence the older writers concluded that the disease was hereditary while in fact they had before them but a wellmarked example of a communicable disease.

Destruction by fire is the ideal method of dealing with the sputum. Each patient should be supplied with a sputum receptacle of a suitable kind into which the expectorated material should be placed and kept until it may be thrown into the fire. Cheapness and convenience are the two requirements of receptacles of this character. After trying a number of those on the market we have adopted at Boulder Lodge Sanatorium one which answers admirably all practical purposes and which costs nothing. It is made from the leaves of old magazines—two or three leaves being rolled into a little cup of cone-shape, about the size and shape of a calla lily, the apex of the cone is turned over for the bottom of the cup and the receptacle is ready for use. It is small, and may be

held in the hand or laid near the patient or slipped into the pocket, and after using two or three times it is thrown into the fire. These cups are readily made by the patient or nurse, the material is always at hand, it is impervious for several hours, and answers fully as well as the more cumbersome and uncleanly articles on the market. These cups are equally well adapted for use in the home. For use at night we have small porcelain granite cups into which papers are folded as a lining. These are placed beside the bed within easy reach of the patient. Each morning the contents of the cups are emptied into the fire, and the cups sterilized.

For those at work, and especially for workmen, some more substantial receptacle may be made of use, such as a small wide-mouthed bottle, which may be slipped into the pocket and readily be cleansed and sterilized each day.

Handkerchiefs and cloths of sufficient value to save from burning should never be used by the patient. Even when the sputum cup is made proper use of, it is necessary to wipe the lips, and for this purpose some soft cloths or pieces of cheese-cloth should be used, after which they may be burned.

It is the duty, both for himself and for those about him, of the patient to see that none of his bacilli escapes the fire.

In the act of coughing, fine particles of germ-laden moisture are expelled from the mouth, and are a source of danger to nurses and attendants or other persons about the patient. Care should be exercised to turn the head from other persons and to place the handcloth over the mouth while coughing.

The bedding and clothing used by the patient often become soiled with sputum and other ejecta containing bacilli. The hands of attendants or others whose duties bring them in contact with such articles are likely to become soiled. The clothing and linen should be such as may be boiled or otherwise sterilized. Bedding should be thoroughly aired before the beds are made, and should be frequently exposed to the sunshine. Attendants must cleanse their hands carefully after rendering any sort of service to the patient or after touching anything about him.

Rooms occupied by the tuberculous must not be used by others and it is little less than suicidal to occupy the same bed with them, particles of sputum and the spray expelled in coughing being specially dangerous in such close proximity. The infection of husband or wife under such circumstances is very common, many such instances having fallen under my personal observation.

The cleansing and sterilizing of rooms that have been occupied by the tuberculous should be thoroughly done. Walls should be wiped, the woodwork washed, all the clothing and bedding removed, aired and exposed to the sun for 2 or 3 days, and linen should be washed and boiled. After thus cleansing, the contents should be returned to the room and hung in such a manner as to expose them to the fumes of the formalin lamp for several hours. After again airing the room it may be reoccupied with safety by other persons.

Sanatoriums for the tuberculous should have bare, polished floors, painted walls with rounded corners, woodwork of plainest type, and furnishings that will catch but little dust.

Tuberculous persons should not expectorate in pastures or in other places where cattle feed as the disease may be communicated to them; neither should they have anything to do with the care of cattle, with the milking of them or with the preparation of foods. Spoons, dishes and other articles from the table or patient's tray should be sterilized by boiling for 20 minutes after each washing.

Personal cleanliness, on the part of the patient should be enjoined; the hands should be washed frequently, the finger-nails closely trimmed and beard closely shaven.

Flies should be excluded as much as possible from the patient's room; they are often guilty of much that has been attributed to other carriers of contagion. Recently, while my assistant was preparing some specimens for the microscope, I observed a fly fall into the cup from which the sputum was taken, and after literally wallowing in it, flew away carrying thousands of fresh tubercle germs on its wings and legs. This little incident served to impress upon my mind the important role which the housefly may play in the dissemination of this disease, and added much to my former opinion of the fly as a public nuisance. The fly should be banished in every possible manner from the home. It is doubtful if the mosquito, concerning which so much has recently been said in pathologic circles, is guilty of half the crimes that could be charged to this common pest.

Kissing.—The mouth and lips of the tuberculous are never free from tubercle bacilli. These germs are still warm and fresh from their resting place in the patient; they have never been exposed for an instant to the light or air, and in the act of kissing, there has been no opportunity for any outside agent to act upon them in their passage from the one who is sick to the one who is well. It is a veritable inoculation of tuberculosis; the germs thus transferred find entrance through the tonsil, fauces, or digestive tract, and in time the early symptoms begin to manifest themselves, while the history of the case gives no clue to the origin of the attack. I am fully aware that it is altogether utopian to condemn kissing, but to kiss the tuberculous often means death to one who at the time may be in perfect health. I believe kissing to be the most dangerous practice in which the tuberculous indulge, and that more persons are infected in this way than in all other ways combined. Kissing is not dissimilar to our feeding experiments with animals, when the fresh bacilli are purposely spread upon the food of animals to be infected. Thus all extraneous circumstances and modifying influences are eliminated, and the active, living germs from the tuberculous subject find immediate entrance into the tissues of the healthy animal.

Tuberculosis in the family from generation to generation may be almost wholly imparted by the family kiss, it being communicated by direct inoculation and with but little else to give rise to the apparent hereditary tendencies of the disease.

Situated as I am, working among this class of patients, I often see them kiss their relatives and friends, and at the particular moment it is often most embarrassing to chide them, but these words that here are written should be taken up by others until every person, whether sick or well, may know fully the danger that threatens from this universal custom.

Many persons apparently in full health have sputa swarming with bacilli. This is a common experience to phthisiologists. These persons, especially if girls, are a source of infinite danger to their acquaintances and friends, and I here, in behalf of health and life, call upon our American girls and women to put aside the foolish practice which has grown up among them of saluting their friends of the same sex with a kiss which has no meaning. Should men indulge such idle folly they would be the subject of ridicule.

This practice is devoid of meaning, is purely formal, is fraught with danger, and is a frequent cause of death. It has nothing to warrant it and should everywhere be condemned. The tuberculous person should always remember that he is a source of danger to others and should refrain from practices that place other lives in danger.

Trailing Dresses.—Dresses that trail upon the streets are carriers of infection. Tuberculous sputum, fresh from the lungs of the tuberculous, is thus often mopped up and carried home, where it may soon find lodgement in some susceptible person, perhaps a little child just creeping

about the floor. Street dresses should always clear the walk; trailing skirts which sweep the dusty and muddy streets, gathering up dirt and filth of every description, are not pleasant to contemplate. Much rather would we think of milady sweet and clean.

The Communion Cup.—The necessary, but as now used, ill-advised communion cup is not free from danger as a carrier of infection. The tuberculous, along with healthy persons, partake of the cup which passes from lip to lip, and clinging to it are accumulations from each. Living, infective bacilli, among other germs, are present and death may thus enter from this sacred obligation. Individual cups alone are proper. In our homes we would deem it improper, and highly so, to offer a cup to another after ourselves partaking from it. No less is it bad taste because done in the sanctuary. Habits do not regulate themselves according to the place in which they are practised. If unsanitary and improper in the home they are none the less so when practised in the church.

Every possible safeguard must be thrown around every individual to protect him from coming into contact with the germs of this deadly disease. If some measures advocated appear harsh or in any way unkind it must be remembered that the good of all is greater than the interests or convenience of the few and that the public health must be conserved at any price.

ITHACA EPIDEMIC OF 1903.

BY

LUZERNE COVILLE, B.S., M.D.,
of Ithaca, N. Y.

Beginning before the middle of January of this year and continuing until the middle of March, Ithaca was visited by an epidemic of typhoid such as had no equal in this country. The city lies upon 8 hills and the valley between (Fig 3). It is supplied by a private water company, from 2 streams. Of these, the water of Six Mile creek was undoubtedly infected. The campus of Cornell University is supplied by water from still another stream, which was clear of typhoid. The city contains approximately 13,000 permanent residents, and houses additionally about 2,800 students of the University. In the first 6 months of the year there were nearly or quite 1,300 typhoid cases. In July and August there were approximately 80 additional typhoid cases, mainly infected from one well, which received water from a broken sewer tile leading from a house in which was a "walking case."

The outburst of typhoid rose rather abruptly from the middle of January till February 2-4. It then fell gradually to February 20, from which time the curve drops gradually and subsides about the middle of March. During this time no person who drank *exclusively* well water, spring water, or artesian well water seems to have suffered from the disease. Of course, a few cases have arisen from transfer infection, but the number is relatively very small. The fact that Ithaca has within its limits about 1,500 wells, many of them in full use, will explain this relatively small number of typhoid cases. For nearly 2 years the city had been warned through chemist examinations of the city water and publication in the daily papers that the city water was unfit for drinking in the raw state, especially in the time of flood. The city Board of Health had especially tried to impress this upon residents by reports made and published in February, March, and April, 1902, when samples of water showed 800, 18,000, and 720 colonies of bacteria per cubic centimeter, for the respective months. For many years the residents have depended for drinking purposes either upon boiled water or upon artesian and spring water brought into the city by venders. It

¹ Read before the New York State Medical Society, at the Second Semiannual Meeting, New York Academy of Medicine, October 14, 1903.

is safe to say that at least 10% to 15% of each class entering the University have "freshman diarrhea" each year, caused largely by the water used.

During the last 5 years in which the University has conducted its student infirmary there has been some enteric fever each year, in the main during the fall months. Some of these are "imported," but as a rule, these patients have not had typhoid originating in town. In the winter of 1900-01 there were 40 to 50 of these student cases; in 1901-02 the number increased to 100 to 150. Of these, only two or three each year have reacted under the Widal test, and these few positive tests have given positive histories of typhoid. Ithaca is not a typhoid town.

Beginning in January, 1903, the type of this enteric fever changed, due to a different strain of infection, and

Fig. 1.—A, report of 961 cases, made to the City Health Board; scale 1-1; the dotted line representing approximate height and distribution if all cases had been reported. B, deaths; scale 1-5; student deaths in light rectangles, the townspeople in black. C, personal observation of cases; scale 1-2; the black rectangles representing fever cases; the — lines the atypical cases.

the outbreak assumed an entirely different character. While in previous years the enteric cases had been of mild course, had not reacted to the serum test, and the patients had recovered in a week to 3 weeks; they now began to run a more typical typhoid temperature curve, and gave the Widal reaction in most cases positively. The patients recovered in 3 to 6 weeks.

Upon the head waters of Six Mile creek lie 2 small villages, Slaterville and Brookton. Along the 12-mile course of the stream its narrow valley is dotted by farms and their houses and barns. In these 2 villages and among these farm holdings there have been not infrequent cases of enteric fever during the past 2 or 3 years. The closets used are those common in the country, and there is every chance in over a score of cases for typhoid dejecta from these outhouses to enter the stream directly. The stream bed is narrow, without storage basin, and its flow, ordinarily about half enough to supply Ithaca. In time of flood or freshet it is what may be termed torrential. A freshet such as took place from December 16 to December 22 would wash down stream a large share of such infection, but would not give a continuous invasion such as is evidenced by the bulk of cases cropping out from February 1 to February 15, nor would it give such a concentrated infecting medium as is evidenced by the outburst of that period. This source of infection can probably be dismissed.

A second source of infection has been considered—that of an Italian colony of laborers employed in the stream bed and encamped upon its immediate margin. This colony left the creek bed before December 1, and did not return until late in the spring. Upon what seems very reliable authority, there was no illness among them. Their presence and their latrines, however, would no better explain the source of infection than the first conditions.

A third cause of infection—in a considerable quantity and for a longer period—would be a person or persons with walking typhoid living in shanties close by the

intake at the pumping station of Six Mile creek. In 2 or 3 of these shanties, lying upon the very outskirts of the town, cases of typhoid occurred early in the winter, as attested by the Widal reaction. In these houses during the winter months the excreta and garbage were thrown out upon the bank of a small stream that leads down to Six Mile creek and empties just below the Ithaca water intake, at a point protected from winter freshets by a bend or bay in the bank of the stream. The winter thaws of December 16-22, January 26-31, and February 2-4, would conveniently bring such typhoid excreta, previously frozen, into the water supply in such a manner, at such times and in such quantities as should reasonably explain the extent of the epidemic both as regards length of infection period and distribution throughout the city pipes.

During late June and early July the Barnes' well infected some 50 persons by means of escape sewage the ingress of which into the well in a half-inch stream could readily be appreciated by means of a lantern dropped into the well.

If we analyze these cases of fever we find them divided into approximately 4 equal divisions or classes—some of each class at some time giving an agglutination test and all giving some if not all the clinical symptoms of typhoid.

Subclass A. Infectious Cases.—I. The subnormal cases. These patients are conscious of no fever at the beginning of the onset, but become subnormal in pulse and temperature and remain so for about 10 days to 2 weeks. They tend to relapse every 2 weeks and may so continue into the third, fourth, and even fifth invasion or incubation. (79 cases.)

II. Cases having a very moderate temperature for a few days followed by subnormal pulse and temperature, and also liable to relapse. Occasionally a second or third relapse will develop a regular typhoid temperature. (64 cases.)

Subclass B. Fever Cases.—III. Short sharp temperature cases of 5 to 10 days' duration, with high pulse. This class simulates grip, is slowly convalesced from, and has only rarely relapsed into typhoid. (75 cases.)

IV. Regular typhoid. These are in the main typical. In the lighter cases, the patients may not present markedly the occipital

Fig. 2.—Distribution of cases as reported to the City Health Board. Compiled by Dr. H. B. Besemer.

migraine, injected eyes, intense pharyngitis, nasal hemorrhage, in the early days, and they are apt to be without rose spots and marked tympanites; and they recover in 10 to 20 days. The severer cases have all the clinical picture of a typical typhoid. (71 cases.)

All these cases of all classes had one peculiar symptom. Every patient had the throat marks of the infection. The pharyngeal walls and especially the pillars of the fauces and the soft palate and the uvula had the dull angry red so common to the "gouty" throat. This remained throughout the relapses or the reinfection periods of the 2 subnormal classes, while in the tempera-

ture cases there was apt to be an extension in the form of a very acute nasopharyngitis. The migraine was usually frontal or occipital, or both, and was especially marked in the regular typhoid class. There was also wellmarked conjunctival injection in any temperature rise. In the subnormal cases especially, the patients had widely dilated pupils and dulled expression. There was regularly constipation throughout the disease.

All hospital accommodations were soon overcrowded. There were 150 trained nurses, at a conservative estimate, employed in the town, and there were 100 or more of moderate training. The patients were in charge of 31 physicians of the town with 8 from out of town. The overcrowding undoubtedly caused a degree of sepsis not common in the disease. Intestinal hemorrhage was a frequent complication, as were also pulmonary edema, pneumonia, and in the very severe cases perforation of the intestine. The records as near as can be ascertained are as follow:

	Cases.	Deaths.	Percent.	Total.
Student typhoid cases in town....	181	13	10	} 9.1%
Student typhoid cases out of town	197	17	8.7	
Cornell Infirmary.....	95	11	11.5	
City Hospital.....	119	8	6.7	} about 5%
City typhoid cases in town.....		42		
City typhoid cases out of town...		7		

The student statistics are that approximately 1,200 students left town; of these nearly half were sick, and of these about 200 had typical typhoid.

Of the physicians one only had typhoid and died. Two or three nurses only had typhoid, and no fatalities among them are known.

Of the 79 deaths, from January to October, there are 20 of which there are no available statistics. Of the others death was directly ascribed as follows:

Typhoid	18	Heart	2
Alcoholism	1	Exhaustion.....	1
Hemorrhage	7	Sepsis	2
Perforation	6	Chronic gastritis.....	1
Pelvic cellulitis	1	Gangrene	1
Acute tuberculosis.....	2	Appendix operation.....	1
Pyothorax	1	Mastoid operation.....	1
Kidneys complicated.....	2	Heart complicated.....	2

In 66 deaths, 3 occurred upon the seventh day, 1 upon the ninth, and 2 upon the tenth. One occurred upon the one hundred and ninety-fourth day. Omitting this and 2 wrongly certified, 63 deaths averaged to have occurred upon the twentieth day.

A word as regards the Widal test: Of nearly 300 patients seen by me, nearly 150 agglutination tests were made. In most of the regular typhoid cases the test was obtained early—from the third to the tenth day—but in a few cases was delayed until the twenty-first, twenty-sixth and twenty-seventh days. Often a positive reaction was followed on succeeding days by negative results. In 5 patients who had given previously a positive reaction, there was a negative result after an average of 63 days. In nine other patients who were previously positive, they remained positive after an average of 73 days. All classes of cases gave positive reactions sooner or later.

	Early tests.	Late tests
I. Subnormal	4 at 43 days	3 at 68 days
II. Mild temperature.....	2 at 18 days	3 at 41 days
III. Simulating grip.....	14 at 14 days	3 at 70 days
IV. Regular.....	35 at 19 days	9 at 73 days

One regular case of severe typhoid persisted in giving a negative reaction throughout its course. It was complicated by erysipelas. (These are most irregular results obtained in the press of practice, but are given for what they are worth.)

One more notable feature is that no plumbers making alterations in plumbing, or connections with the mains

in the vicinity of typhoid houses, nor any sewer station operatives, so far as can be ascertained, had typhoid fever.

In the later and small epidemic in July, only about 7 or 8 patients can trace their typhoid to a possible infection through the medium of flies.

This epidemic is remarkable for the following reasons:

1. The absence of sure causal proof.
2. The sharp onset and comparatively abrupt ending of the epidemic.
3. The great variety in its course, and the large percentage of atypical cases.
4. A cyclic recurrence of symptoms at intervals of 14 days, or relapses, or reincubations from autoinfection in the atypical cases.
5. Many cases ran a severe and septic course. (There was much intestinal hemorrhage and pneumonia.)
6. The relatively small number of relapses in the typical cases.
7. While many people of the Cornell University campus drank city water occasionally, only a very few had a regular type of typhoid.
8. Those who drank exclusively of other than city water escaped infection.
9. Bathing in city water, and the use of city water

Fig. 3.—Map of Ithaca, showing Six Mile Creek entering from the southeast and giving the location of the dam (a) and pumping station (b) of the Water Works Company.

for general utility and culinary purposes caused no typhoid.

10. Outside of families and the direct care of the sick, few cases of transfer infection are known.

11. The milk-supply was not infected.

12. Through the extreme care of latrines and out-house collections, practically no epidemic resulted through flies during the summer months.

13. The almost total immunity of physicians and trained nurses.

14. The deathrate was relatively much higher among the adolescent students than among the townspeople.

15. The comparatively high average age at death—29.6 years.

16. Many who had enteric fever and typhoid during the past 2 years had typhoid this year.

17. The relatively low deathrate under the conditions—6.6%.

18. The large number of cases—over 1,300, and probably over 1,400 if the facts could be ascertained.

19. A practically average percentage deathrate for all physicians.

20. A vote of 1,335 to 30 upon the third of March, in favor of municipal ownership of the city water supply,

and the establishment both of a filtration plant, and of an artesian water supply.

21. The almost total exemption of the city from typhoid now, after a small outbreak during the summer.

Drs. Emil M. Chamot, Veranus A. Moore, Benson A. Cohoe, and Mervin T. Sudler, of the University, have given most invaluable aid both during the epidemic and since. Drs. H. Burr Besemer and Edward Hitchcock, Jr., of the city Health Board, have aided in compiling the statistical tables and maps.

7.—**Empyema of the Antrum.**—O. N. Heise is impressed by the few references, to the difference between cystic and true empyema, the one being due to a dental cyst, the other a true infection of the antrum of dental or nasal origin. These cysts press on the floor of the antrum until the bone is finally resorbed, leaving only the periosteum and mucous membrane of the antrum as a covering, the cyst then filling the chamber completely, raising outer and inner walls and the roof. Many antral cases are due to primary infection from some accessory cavity. Dental abscesses and caries and even filled teeth often cause nasal disturbances. It is easy to overlook a diseased condition of the roots. Extraction is often a prime factor in cure. The relationship between diseased conditions of the upper jaw and antral troubles should be considered more frequently than it is. [H.M.]

8.—**The Röntgen Ray.**—A. D. Bevan believes the Röntgen ray is indicative in certain superficial epitheliomas, as a post-operative treatment in most carcinomas, and in inoperable cases as a justifiable piece of experimental work. The dangers are from serious burns even in expert hands, and from losing valuable time in using the Röntgen ray when greater chances of cure are offered by surgical removal. The amount of damage for which this is responsible far outweighs the good so far accomplished. [H.M.]

9.—See *American Medicine*, Vol. V, No. 22, p. 863.

10.—**Syphilis in the Negro.**—F. Jones frequently encounters simultaneously in the negro both the primary and secondary manifestations. The high mortality of pulmonary tuberculosis in this race is due to the damage already wrought by syphilis. Syphilis also causes enormous accumulations in the pleural cavities. The prevalence of heart disease is due to the same cause. Acute syphilis produces acute endocarditis, from which lesions both valvular and muscular may arise in their most severe forms. Sometimes the disease seems to spend its force on this organ. The writer reports 43 cases of stricture of the rectum, 47 being in women, and believes that this is a more frequent cause of pronounced constipation than supposed. This is due to syphilitic infection to which the rectum in women is more exposed than in men. [H.M.]

11.—**Rapidly Growing Sarcoma of the Femur.**—C. M.

Nicholson describes sarcomas of central and peripheral origin in the long bones, and reports a case of the peripheral variety in a child of 8, requiring amputation at the hip-joint 5 weeks after the first appearance of symptoms, the leg affected being 3 cm. greater in circumference than the other. 6. What was the Cause of Death? A. ELLIOTT PAINE.

2.—**Acute Flexion of the Gallbladder as a Cause of Biliary Colic.**—A. T. Cabot reports 2 cases. An otherwise healthy woman of about 50 had for years been subjected to attacks of pain in the right hypogastric region. She, in addition, had the other ordinary symptoms of biliary colic, except there was no definite history of icterus. Operation being consented to, the gallbladder was found rather long, with its fundus extending below the edge of the liver, and the pressure of the ribs carried its fundus upward and inward, producing a distinct bend or kink in the gallbladder. When the fundus was drawn downward this bend was effaced, but it reproduced itself when the gallbladder was allowed to fall back; there were some slight adhesions. The gallbladder was opened and no stone found. To obliterate the kink, the gallbladder was drawn outward and attached to the peritoneum. Prompt recovery from the operation followed, and the most annoying symptoms were promptly relieved. However, some disturbance persisted and later evidence of appendicitis appearing the appendix was removed, since which time the patient has been entirely free from pain. The second case was an otherwise healthy man, who likewise presented the general symptoms of attacks of biliary colic, but there was no icterus. These attacks having been repeated several times, operation was advised and consented to. The gallbladder was found long and lax; it projected beyond the edge of the liver, and being attached to that organ up to the very edge, made, by its weight and downward pull, a distinct sulcus in the lower edge of the liver. Cholecystectomy was done; no stones were found in the gallbladder, and the patient made a complete recovery. The author is of opinion that the kinking of the gallbladder in both these instances produced the symptoms. In such cases he believes it is best to completely excise the gallbladder. [A.B.C.]

3.—**Chronic Sphenoidal Sinusitis.**—A. E. Rogers, in his experience in the Massachusetts General Hospital, has come to the conclusion that chronic sphenoidal sinusitis occurs much more frequently than is generally supposed. He found on examining 600 patients, that 29 were cases of accessory sinus disease, or nearly 5% of all who came to the throat department for treatment. Chiari and Lichtwitz report an average of only 2%. Of these 29 cases he found the antrum of Highmore affected 4 times, the frontal sinus once, a mixed frontal and ethmoid twice, the anterior ethmoidal 3 times, the posterior ethmoidal twice, the sphenoidal sinus 16 times, and a mixed posterior ethmoidal and sphenoid once. This places the empyema of the sphenoid at the head of the list, which does not agree with the majority of clinical observations in placing the maxillary sinus as the most commonly diseased. Specific directions are given by the author as to how to reach the sphenoidal sinus and determine whether or not there is a pathologic condition; likewise his operative procedure upon such cases in which operation is necessary, is detailed at some length. Eleven cases, regarded as somewhat typical, are described in detail. [A.B.C.]

5.—**Brain Hardened by Kaiserling's Method to Show the Track of a Bullet.**—William F. Whitney reports that a man had shot himself with a 32-caliber revolver with suicidal intent. Two shots had been fired, both striking the frontal bone, only 1 of which penetrated the skull. In spite of operation and active treatment the patient died some hours after being admitted to the hospital. The interesting features of the

case was the postmortem treatment of the brain to preserve it for medicolegal and other purposes. It was hardened in bulk in Kaiserling's fluid for 2 months. It was then cut in a series of sections each 1.5 cm. thick and the track of the bullet located as follows: It entered at about 4 cm. from the front of the right anterior lobe, passed directly across, traversing both lobes. In the left one was a cavity the size of the end of the thumb, filled with blood clot and disintegrated brain substance. This opened upon the surface at the point where the trephine wound had been made. From this cavity the track turned almost at right angles and proceeded directly backward, passing through the white substance of the left hemisphere and along the upper part of the convolutions of the island of Reil, in the middle part of which it was found to be lodged. [A.B.C.]

Medical Record.

January 2, 1904. [Vol. 65, No. 1.]

1. A Plea for Justice to the Tuberculous. S. A. KNOFF.
2. The Diagnostic Significance of Certain Reflexes and Tendon Phenomena. H. OPPENHEIM.
3. Commentaries upon Lues and Leprosy as Subkatabolic Diseases. HOMER WAKEFIELD.
4. Diagnosis of Acute Lobar Pneumonia. STEPHEN SMITH BURT.

1.—Justice to the Tuberculous.—S. A. Knopf appeals against official, private, and professional phthisiophobia. He discusses the injustice and inhumanity of the Marine-Hospital regulation on the subject, and the almost universal protest on the part of the medical profession. He also scores the infamous Goodsell-Bedell law, which is practically prohibitive of the establishment of tuberculosis sanatoriums anywhere in New York State, and records the deprecatory resolutions of the New York Academy of Medicine and other medical societies of the State. Private phthisiophobia has resulted partly from the official and partly from the excessive caution of the insufficiently educated. The difficulty of obtaining work leads to the concealment of incipient cases, and thus overcaution defeats itself. In answer to professional phthisiophobia, as represented by Qaxe's paper in the *New York Medical Journal*, the writer quotes the opinion of leading specialists and others, giving a decided negative to the charge that there is a greater tendency to immorality and crime than among the well or those afflicted with other diseases, and that the average tuberculous patient is inclined to brute selfishness, to loss of self-control, and distortion of ethical perceptions, many inclining to the belief that these sufferers are above the average in their mental and moral character. Insanity invites tuberculosis through lowering of the vitality, close confinement in asylums and prisons, lack of exercise, depressing environment, close contact with inmates already tuberculous, and lack of facilities for treatment. There is urgent need for reform in these institutions. Education is the only method of combating phthisiophobia. The perfect safety of contact with an individual who takes care of his sputum should be made known to all. [H.M.]

2.—Cerebral Reflexes and Tendon Phenomena.—Professor H. Oppenheim, of Berlin, calls attention to the almost universally constant presence of the knee-reflex phenomenon in health. It may be absent in apparently healthy children of syphilitics; but later symptoms of hereditary syphilis may supervene. Mechanical conditions such as fat, genu valgum, edema, etc., may prevent the manifestation of the reflex. Under other conditions any exaggeration or diminution of this phenomenon is indicative of a pathologic condition. The achilles reflex or heel phenomenon is not fully appreciated. With the patient in the kneeling position the phenomenon in the normal state consists in plantar flexion of the foot when the achilles tendon is percussed. It is almost constant in health, and its absence is important, in the absence of trauma, a previous sciatica, diabetes, etc. The loss of heel-reflex usually long precedes the loss of knee-reflex in tabes. The Babinski reflex is dwelt upon at some length and a number of its varying manifestations explained. The author directs attention to a reflex first noted by himself. If, in health, the inner aspect of the leg be stroked, tapped or pinched, there will be either no movement, or flexion of the toes will occur; but in affections of the pyramidal tracts a dorsal flexion of the toes and of the foot

occurs. It thus forms a valuable adjunct to the Babinski test. [A.B.C.]

3.—Syphilis and Leprosy as Subkatabolic Diseases.—

In conclusion, Wakefield says in substance that in the treatment of syphilis and leprosy, parasitocides, *per se*, however powerful, unless they are active oxidants, are of no value, but active oxidants are of the greatest value, even if devoid of parasiticide properties. Mercury, in the primary stage of syphilis, does not even destroy the virus, as is attested by the later appearance of the secondary and tertiary manifestations. Potassium iodid accomplishes a similar purpose as an oxidant in syphilis, leprosy, and in cancer, though it is most valuable in the former. Agents producing hyperemia of the tissues are of greatest value. Erysipelas has been mentioned; the bites of venomous serpents, scorpions, hornets, etc., when not proving fatal, are even curative; which suggests the hypodermic injection of attenuated venoms, to the same end. Hot baths, exercise, cardiac stimulants, oil massage, using the oil of highest reduction (oxidation) power, and oil internally, which has been found so efficient in leprosy, have all been found of value. Theoretically, an arrangement by which Röntgen or ultraviolet rays of light, or high-frequency currents could be administered to the entire body for long periods daily, would be most efficacious. [A.B.C.]

8. Delayed Secondary Hemorrhage Following Amygdalectomy: Report of Two Cases. RICHMOND MCKINNEY.

1.—Etiology of Bronchopneumonia.—L. A. Conner says the name bronchopneumonia does not indicate a single infectious disease, but is used to designate those inflammations of the lung parenchyma, of whatever etiology, which have their origin in the bronchial walls and which therefore bear a constant relation to such bronchi. With respect to etiology he considers 2 great classes—primary and secondary. The secondary cases are divided into 3 groups: 1. Those cases complicating or following the acute infectious diseases, and seen especially in children. 2. Those developing in the course of various chronic and debilitating diseases. 3. Aspiration pneumonia. Holt found that among 426 cases of bronchopneumonia in children 97% occurred during the first 3 years of life. Primary cases are very rare in adults. In the aged, the primary form is occasionally seen, but by far the greatest number of cases develops in the course of the various chronic diseases common to that period of life. Among the acute infectious diseases complicated by bronchopneumonia measles stands first. Influenza, diphtheria, whoopingcough, and scarlet fever, are especially mentioned. It is also a complication of typhoid fever, smallpox, erysipelas, and even varicella and German measles. Chronic nephritis, chronic diseases of the heart, gout, cerebral hemorrhage, and the various surgical affections, such as fractures are the conditions in group 2 most frequently complicated by bronchopneumonia. Aspiration pneumonia is common in all conditions of stupor and unconsciousness, such as cerebral hemorrhage, meningitis, and the like, when the normal sensitiveness of the larynx and trachea is lost and when the act of swallowing is imperfect. Among the cases of primary bronchopneumonia the bacterium most frequently found is *Diplococcus pneumoniae*. Next, but far below it in point of frequency comes *Streptococcus pyogenes*, either alone or combined with other bacteria. Much less frequently than these two have been found, separately or in various combinations, the pyogenic staphylococci, *Bacillus pneumoniae* of Friedländer, the influenza bacillus, *Bacillus pyocyaneus*, *Micrococcus tetragenes*, and others. In the bacteriology of secondary bronchopneumonia the bacterial list includes the same names, together with a number of others, such as *Bacillus diphtheriae*, *Bacillus typhosus*, *Diplococcus intracellularis meningitidis*, etc. [C.A.O.]

2.—Point of Election in Tuberculosis.—According to J. O. Cobb, the explanation for the constant deposit of bacilli and foreign matter lies in the fact that the vis a fronte by the great veins and lymph vessels in the angles of the neck causes enough suction to create a counter lymph current and an area of lymph stasis in the apices of the lung. A bacillus falling within this zone of lymph stasis would become arrested far quicker than elsewhere in lung tissue. In bovines, as well as in man, the pulmonary deposits of foreign matter are anatomically the same as for tubercle bacilli. [C.A.O.]

3.—Nose and Throat Operations.—Justus Sinexon calls attention to the accidents and complications following operations on the nose and throat. He believes that the laryngologists and rhinologists of today are at fault, in that they seldom attempt to correct redundant tissue or faulty secretions by constitutional treatment, but at once resort to the knife or cautery, and that they have an almost total disregard of the anatomy or physiologic functions of the nose or throat. When the necessity of operative interference in the nose and throat is unavoidable, care should always be exercised, regardless of the technic employed, that the repair should be accomplished with as little cicatricial tissue as possible. Another source of danger is that when the operation is not fully completed, fragments of tissue and portions of bone or cartilage are allowed to remain, thus impairing drainage, interfering with the reparative process, and offering a possible source of infection. [C.A.O.]

4.—Fat Necrosis.—The case reported by V. B. Jackson is of interest mainly on account of the large tumor that was formed. The patient, a man of 56, had a chill, attended with intense nausea, vomiting, and severe pain in the epigastrium. There was slight fever and constipation. A distinct tumor was noticeable lying midway between the umbilicus and ensiform cartilage. It was the size of an ordinary fetal head, somewhat movable, and very tender upon slight pressure. An exploratory incision was made, the transverse colon lay in a sulcus at its upper part, the duodenum and ileum being intimately attached below, and the excessive fat of their omentum and mesentery, which was diseased and lumped together, apparently made the bulk of the mass. A specimen showed the mass to be one of typical fat necrosis. It is the opinion that the mass was formed from a subacute pancreatitis, and that the acute symptoms were not unlikely induced by an acute gastroduodenitis. The patient made an uneventful recovery. [C.A.O.]

5.—Laryngeal Complications in Typhoid.—Homer Dupuy reports a case of submucous laryngitis complicating typhoid fever in a girl of 20. High tracheotomy was followed by great relief and subsequent recovery. The points of interest are the prompt relief, during 9 hours, which followed the local use of adrenalin, the alarming hemorrhage which occurred a few hours after the operation and presumably due to hypostatic congestion of the right lung, the action of adrenalin given internally which the author believes arrested the bleeding in this instance, and the complete restoration of the cricoarytenoid joint movements, which guaranteed the normal respiratory and phonatory functions of the larynx. The 25 collated cases mentioned in this article, which have been reported in the last 58 years, afford eloquent proof that the subject of typhoid affections in the larynx calls for general recognition. Evidence, bacteriologic and clinic, strongly supports the view adopted by the majority of observers, that the laryngeal involvement in most instances is a direct typhoid infection. A high deathrate, as shown by statistics, when this complication exists, teaches the salutary lesson of always examining the larynx when the danger signals of hoarseness, dyspnea, or dysphagia set in. The favorable results which follow operative interference offer such a contrast to the high mortality without operation that there can be but unanimity of opinion as to its propriety. Tracheotomy is the most approved because in most cases the only possible surgical procedure which can save life. [C.A.O.]

6.—Prevention of Premature Baldness. John Gilbert maintains that the tight hat band and the impervious material from which the head gear of many civilized persons is constructed, are responsible for cases of baldness, especially of the premature variety. The devices advocated by him consist of cork or other resilient material upon a backing of some metal;

the whole to be applied at intervals to the hat band in juxtaposition to the head, thereby confining the pressure to certain parts or sections, leaving the intervening space free to allow the free ingress and egress of air, and to relieve the pressure on the blood-supply. [C.A.O.]

7.—Castor Oil Treatment of Typhoid.—C. C. Bass summarizes the results in 79 cases of typhoid fever treated with castor oil. In the majority of these cases no medicine except castor oil was given. All were given an abundance of pure drinking water. The diet was strictly liquid, generally milk, and sometimes predigested food. No deaths occurred. There occurred 3 hemorrhages. The shortest duration of fever was 12 days; the longest, a case which relapsed, 44 days. The average duration of fever was 16½ days, counting from the first day of the headache, malaise, etc., until the temperature reached normal. Bass begins promptly with a dose of pure castor oil every 12 hours, regardless of the stage of the disease. The dose should be regulated so as to cause 1 or 2 actions, and will vary from 1 dr. to 8 dr., depending upon the patient, the stage of the disease, and the condition of the bowels. [C.A.O.]

8.—Secondary Hemorrhage after Amygdalectomy.—Richmond McKinney reports 2 such cases in boys aged 7 and 10 years respectively. The hemorrhage in each case occurred 4 days after the operation; it was oozing in character and venous. [C.A.O.]

Medical News.

January 2, 1904. [Vol. 84, No. 1.]

1. The Management of Typhoid Fever Epidemics. GEORGE A. SOPER.
2. Anomalies and Difficulties of Diagnosis in Typhoid Fever. HENRY L. ELSNER.
3. Management and Treatment of Typhoid Fever. EGBERT LE FEVRE.

5. Excision of the Frenum Preputii Following Laceration During a Suspicious Intercourse. CHARLES C. MILLER.
6. Chickenpox Concurrent with Smallpox. PHILIP D. BOURLAND.

1.—Management of Typhoid Epidemics.—G. A. Soper reminds us that we attribute to health boards a knowledge they do not possess, and then excuse them from responsibilities the law places on them. It is customary for 1 member to be a physician, and beyond this no scientific knowledge is required and no remuneration is given. Theoretically, the health officer employed, directs the active work. His salary is less than a dollar a day, and a scientific training in sanitation can scarcely be acquired in this country. The responsibility for typhoid epidemics lies ultimately in many cases with our universities. In atypical cases of typhoid provisional diagnosis should be promptly reported, and on the seventh day a Widal test made. When aid is needed to control the epidemic the State board should be called on, and its representative provided with ample power. The 30 days required for dissolving an incompetent local board should be shortened. Except in extreme cases the State's expert should act only as an adviser. Maps should plot the location of cases, and tables embody results chronologically. As disinfection on a large scale is required, the board should furnish the lime and bichlorid. Urotropin should be used for the bladder. [H.M.]

2.—Anomalies and Difficulties of Diagnosis in Typhoid.—H. L. Elsner thinks no other acute infection so atypical, and few confer so short an immunity. Incubation may be long with vague symptoms, or we may have early hyperpyrexia with profound involvement of the nervous system. Among the most malignant cases are those met in drunkards, and in those nervously reduced, which develop cerebrospinal meningitis and die before the tenth day. Typhoid is a hypotensive disease. As it advances pressure may fall to 100 mm. or lower. At no time is it high without complications, usually abdominal. During the first stage relative lowering and disproportion is more diagnostic than dicrotism. There are sometimes sudden drops to normal temperature without hemorrhage or perforation. In most cases in the prodromal stage fibrillary twitching of the tongue is characteristic. The diagnosis of typhoid must be surrendered if the patient has repeated chills. There are few cases in which chilly sensations are absent. The least valuable of prodromal symptoms is nose-bleed. The writer has detected an enlarged spleen in all cases, but not by palpation, and eruption in all but 8 cases. With scarlatiniform

eruptions blood cultures reveal the specific bacilli. In 2% of cases a vesicle caps the roseola. In 2 cases seen by him there were severe hemorrhages before the eleventh day. Subjective and objective symptoms of perforation are not always associated with rupture of an ulcer, the peritoneum being protected by adhesions. There may be effacement of liver dulness without perforation. Peritoneal inflammation causes rise of blood-pressure. There should be daily observations of pressure. The differentiation of nephrotypoid from a preexisting chronic nephritis depends on pressure. With evidences of endocarditis we may presume the absence of typhoid. [H.M.]

3.—Management and Treatment of Typhoid.—E. Le Fevre advises having 2 beds in the room so that there may be daily airing and sunning. The physician should by inspection see that his orders as to cleansing after defecation and urination are carried out. In no other disease do we so fail to adapt diet to individual needs. With milk exclusively, the stools contain more undigested food than with a mixed liquid or semiliquid diet containing the same amount of proteids, carbohydrates, and fats. Milk is deficient in carbohydrates, resulting in a condition of partial starvation, in which the proteids of the body must make up the deficiency with progressive loss of weight. It must be shielded from this by giving carbohydrates and other energy sustaining foods. The increased coagulability of the blood in the later weeks depends on increase in lime salts in the blood from the calcium oxid of cows' milk and the lime water used at times to dilute it. This suggests partial decalcification by citrate of soda. The physician should be capable of giving definite instruction as to the preparation of food. None should be given which cannot be passed through a fine wire sieve. Water should be given ad lib. and may be acidulated with HCl or orange and lemon juice or flavored with wine. It is rarely wise to give more than 2 pints of milk daily. This also may be variously flavored, and stale grated bread or baby foods may be added to it. Carbohydrates may be given as soups of oatmeal, rice wheat, barley, tapioca, or sago alone, or with bouillon. With milk and eggs they cause flatulency. Egg combined with milk is difficult of digestion. Egg water may be given. The yolk should be given only after subsidence of the fever. Gelatin protects the proteids of the body and is valuable in hemorrhage. Salines and castor-oil are the best cathartics, and salol the best disinfectant. Brisk rubbing should accompany the application of cold. Strychnin should be reserved until the nervous centers are affected. Alcohol stimulates the heart and retards emaciation. Nitroglycerin should be given only when tension is high. [H.M.]

4.—Chlorin as an Antiseptic.—Douglas Stewart gives the results of his experience with chlorin and other antiseptic agents. Taking mercuric chlorid 1-1,000 as a standard and anthrax as the germ, various preparations of chlorin have been found to make a good showing. The 2 best known chlorin solutions are the liq. sod. chlorat. of Labarraque and the liq. pot. chlorat. of Javelle (Javelle is a mill, not a man). By omitting water from the Labarraque we obtain the wellknown technic of washing soda and calx. This with anthrax gave 6 positive cultures out of 6 trials. It worked well, however, against molds, gave quite as good results and did not attack the hands so much when one-third (by weight) of the carbonat. potas. was substituted for the carbonat. sodæ. To eliminate soap from our technic take a heaping teaspoonful of calc. chlorat., of table salt and of aq. ammoniac, mix in a quart of cool water, bleach and cleanse the hands therein and they will often be sterile. Give special attention to the nails with powdered pumice, stick and brush. When properly performed, one should not get more than 2 positives out of 12 attempts, although this washing is merely preparatory. Rubber gloves boiled for 15 minutes were placed on a sterile plate in the open air and 2 cultures made from them every 3 minutes. One showed both cultures positive on the second culture, i. e., at the end of 3 minutes. The other glove took at 21 and 24 minutes. He knows of no methods in general use which will sterilize a vulva. All fail when tried at the bar of the culture media. Recently his advice to pregnant women is to daily wash the mons veneris and private parts with water 2 quarts, a heaping teaspoonful of calx, of salt, and a half teaspoonful of pot. carb. Let it dry on the skin. Without being too positive with but 3

vulvas, 1 was sterile after the second washing, 1 after the sixth, and the third was confined too soon to determine. [A.B.C.]

5.—Excision of the Frenum Preputii Following Laceration During a Suspicious Intercourse.—C. C. Miller holds that the danger of syphilis after intercourse with a prostitute is great if there be any abrasion of the penis. The abrasion most common from such intercourse is laceration or rupture of the frenum. Under such circumstances, if the patient is seen within 24 or 48 hours, his practice is to completely excise the frenum, making a gutter in the glans at the site previously occupied by the insertion of the frenum. This gutter is closed with a continuous suture of catgut. If the foreskin is redundant, circumcision is done at the same operation. Excision of the frenum is justified on the ground that if ruptured it will atrophy, and is therefore useless; it removes a seat of probable inoculation, and probably prevents the patient from contracting syphilis. The history of syphilitic infection leads to the supposition that the virus is taken into the general circulation but slowly, hence as a preventive measure it is rational. If but 1% of such operations prevents an attack of syphilis it is justified. In 5 patients so treated the author has seen no syphilis, though a chancreoid in one instance occurred at the site of operation. [A.B.C.]

6.—Chickenpox Concurrent with Smallpox.—P. D. Bourland reports an epidemic of chickenpox, and notes that the concurrence of smallpox in no way caused the course of his cases to depart from the type. Vaccinated and unvaccinated showed equal susceptibility and a similar course. None had ever been exposed to smallpox. No adults were attacked. Previous attacks in 5 children again exposed conferred immunity in 4. Smallpox and chickenpox are distinct entities and neither influences in any way the other. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Levulose Diabetes.—As a general rule, the sugar excreted by diabetics is dextrose; but in rare instances, it is entirely or in part levulose. The number of cases of levulose diabetes is still very small. An interesting one has just been reported by W. Schlesinger.¹ The patient, a girl of 15, passed a large quantity of levulose. She had had polydipsia and polyuria, and suffered from weakness, but was not emaciated. Attacks of psychic excitement were frequent. The administration of levulose caused a marked increase of this sugar in the urine; while under phloridzin the levulose disappeared and dextrose was excreted. This point is of interest in connection with the theory of phloridzin diabetes. As the patient had levulosuria, she presumably had levulosemia; and according to the prevailing theory that phloridzin merely renders the kidney permeable to the sugar in the blood, she should have had levulosuria. The appearance of dextrose, however, shows, in the author's opinion, that the accepted theory is not tenable. Of the 5 cases of spontaneous levulosuria reported, the youngest was 15, and the oldest 51. In 4 there were typical diabetic symptoms. The cases were usually mild, and did not pass into a severe diabetes. The presence of levulose has been repeatedly demonstrated in the urine of ordinary diabetic cases. Regarding the origin of the levulose, Schlesinger believes that it is formed in the body, and not ingested; that it is produced in the tissues and in the blood, out of dextrose; and that it is probably a normal product that in cases of levulosuria is not utilized; although there may in some cases be an overproduction of the substance. Levulose may be demonstrated in the urine by means of the Seliwanoff reaction and of the spectroscopie.

REVIEW OF LITERATURE

Action of Diphtheria Toxin on the Circulatory Organs.—This paper is the second one contributed on this subject by

¹ Arch. für exper. Path. u. Pharmak., Bd. 1, Hfte. 3 and 4.

Karl Ritter-von Stejskal.¹ In it he shows that intravenous injection of large quantities of toxin in the dog produces effects both on the heart and on the bloodvessels. The heart is first irritated and then paralyzed. The nervous apparatus of the heart is also influenced, the reflex control of the heart over the circulatory apparatus being lost. The effect of the toxin on the bloodvessels varies from a slight loss of vasomotor tone to an absolute paralysis. These effects on both sides of the circulatory apparatus occur simultaneously, and the cardiac paralysis can not be exclusively attributed to the vasomotor paralysis. The latent period and action of the poison depend not only upon the dose of toxin, but also upon the resistance of the animal. The author could not demonstrate an injurious influence of the vasomotor paralysis on the heart, which theory is maintained by Romberg. It cannot be denied that an imperfect filling of the coronary arteries, as a result of lowered blood-pressure, may have some influence on the heart; but this seems unlikely, as it seems more probable to assume that a diminished blood supply will first affect the respiratory center, and later the heart. [B.K.]

Comparison Experimental Studies of the Virulence of Differently Bred Tubercle Bacilli of Human Origin.—Moeller² finds that by passing the human bacilli through guineapigs, the tubercle bacilli from these animals are much more virulent for guineapigs than human bacilli inoculated directly into these animals. He says the bacteria having once passed through the animals adapt themselves to that soil, and henceforth become more virulent. Moeller also finds that the tuberculin, the product of avian, blindworm tuberculosis, and other acid fast bacilli, acts similarly upon cattle and human beings, and yet avian, human, and blindworm tuberculosis are separate types. It is a question of a group reaction, a chemic process, characteristic of the whole group of acid fast bacilli. In closing, Moeller says after the passage of the bacilli through guineapigs we are no longer dealing with human tubercle bacilli, but with the tubercle bacilli of guineapigs. [J.F.]

A Contribution to the Study of Splenic Anemia.—S. M. Zypkin³ reviews the literature on this subject, and gives the salient points of cases reported by Stümpell and Müller. He gives in full detail the history and autopsy notes of a case of splenic anemia in a 41-year old woman. This patient presented a complex of symptoms simulating both pernicious anemia and pseudoleukemia. Blood examination showed 2,900,000 red blood cells, 23% hemoglobin, and a normal number of white blood cells. The differential count of the latter was as follows: Polynuclear neutrophiles, 54%; eosinophiles, 2%; large lymphocytes, 27%; small lymphocytes, 12%; mononuclear cells with nongranular protoplasm, 6%. The lymph-glands were not enlarged, but the characteristic splenic tumor was present. Postmortem examination showed fatty degeneration and infiltration of the liver cells and considerable atrophy of the mucous membrane of the alimentary tract. The bone marrow showed the typical changes of pseudoleukemia. Zypkin places this case midway between pernicious anemia and pseudoleukemia, although it is more closely related to the former than to the latter. He concludes that the severer types of blood diseases are closely related to each other, and that pernicious anemia, splenic anemia, and pseudoleukemia are different stages of lymphatic or myelogenous leukemia. [W.E.R.]

Caisson Illness and Diver's Palsy.—An exceedingly valuable and exhaustive experimental study of the effect of compressed air and of oxygen has been made by L. Hill and J. J. R. Macleod.⁴ The results are tabulated under 9 headings, including the effect on the respiratory and other systems, circulation, etc., the effects of decompression and the rules of safe working for caissoniers and divers. They find that the cause of caisson sickness is the escape of gas bubbles in the bloodvessels and tissue fluids on decompression. These bubbles can be seen postmortem in the bloodvessels, heart, retina, aqueous humor, connective tissue, spaces, etc. The alimentary canal is

blown out with gas and cyst-like cavities are produced in solid organs. The practical suggestions regarding the precautions to be observed with workmen are of great value. From their study in conjunction with records of caisson sickness the writers conclude that men selected for high pressure work should be small, spare and wiry and not older than 20 to 25. They should be total abstainers and abstemious in all their habits. The longer the shift the slower should be the decompression, and the higher the pressure, the shorter should be the shift and the longer the decompression. The ventilation of the caisson or diving apparatus should be very free, the temperature of the air being about 60° F. The men should remain quiet for an hour or so after decompression and be recompressed on any sign of sickness. The writers are of the opinion that by proper choice of men and regulation of the shift and decompression period, work could be carried on without loss of life at a depth of even 200 feet, that is about 7 atmospheres pressure. [A.G.E.]

GENERAL SURGERY

MARTIN B. TINKER
A. B. CRAIG C. A. OBE

EDITORIAL COMMENT

The effect of ether anesthesia on the kidneys has been supposed by some to be very irritating, so much so that ether should never be given to patients suffering from nephritis. Influenced by the statement of a surgeon of experience that he would not operate in the presence of albumin and casts except in cases of great necessity Dr. John C. Munro¹ investigated the records of 4,185 patients who have been treated in the surgical wards of the Boston City Hospital within 3 years. He found albumin and casts in the urine of 500 patients who were not suffering from obvious renal degeneration. Practically every form of injury and disease was included in the series, the majority being of a serious nature. Of these patients 60% underwent operation, 12% suffering from fracture, and in many cases etherization was for long operations. The cause of albumin and casts was difficult to determine. The use of alcohol, insufficient or improper food, and hard work are suggested as possible causes of renal irritation. Sepsis seems to be a factor of some importance, for in a number of cases the albumin and casts disappeared as soon as drainage was established. The recoveries were as satisfactory as could be desired and there were no complications but which might adequately be explained on grounds independent of renal lesions. Postmortem examination showed no condition which would indicate that the kidneys were the cause of the fatal result except in 2 cases out of 63. Munro concludes that we should expect evidence of renal irritation in over one-third of the surgical patients in a municipal hospital. A trace of albumin with or without hyaline and granular casts, unattended by other evidence of renal degeneration should not influence the prognosis in surgical disease or operation. The proportion of young and otherwise healthy people affected is as great as in adults. Albumin and casts alone are apparently no contraindication to the administration of ether. This paper seems of great practical importance. Ether is now generally acknowledged to be a much safer general anesthetic at the time of operation than chloroform or any of the other usual general anesthetics. A considerable number of surgeons, however, have adhered to chloroform as the best general anesthetic because they have believed that the effect of ether on the kidneys and lungs is dangerous enough to counterbalance the greater safety of ether at the time of operation. This opinion does not seem to have been founded on any very definite information and up to this time few if any have taken the trouble to study the effects of ether anesthesia in a large series of cases as Munro has done. Very often careful study of cases and accurate observation give us

quite a different view of a condition than we have gained by more superficial observation. No doubt in many cases the albumin and casts, which Munro shows, exist in a considerable proportion of cases quite independent of the use of any anesthetic, have many times been unjustly attributed to the use of ether. If as his contribution seems to show, ether usually has no effect on the kidneys, its much greater safety at the time of operation certainly entitles it to the favor which it has enjoyed with a large proportion of American surgeons, in spite of the contrary opinion of most British and Continental surgeons.

REVIEW OF LITERATURE

Perforating Gastric and Duodenal Ulcers.—B. G. A. Moynihan¹ states that we have to deal with acute, subacute, and chronic ulcers. In the acute form the floor of the ulcer gives way suddenly and completely, and stomach contents pour out and produce sudden, alarming symptoms, which terminate fatally in almost all cases, unless speedy treatment is instituted. In the subacute form, owing to the small size of the ulcer, or the emptiness of the stomach, or to plugging by omentum or lymph, escape of stomach contents is small. The symptoms may be quite as sudden and alarming as in the acute variety, but the patient is much more likely to recover. In the chronic form, perforation takes place slowly, and a protective peritonitis develops ahead of the perforation. Escape of stomach contents is therefore local and may lead to perigastric abscess. Chronic perforation occurs most frequently on the posterior gastric wall; acute and subacute perforating ulcers are most common on the anterior wall. Recovery may occur under medical treatment in any of these forms, but in the acute and subacute forms the danger is so infinitely greater than from operation that the latter should be done without a moment's delay. When in doubt as to diagnosis, the author relies much on rigidity of the abdominal muscles. In women, about the time of the climacteric, false symptoms of perforating ulcer may occur without known cause. Absence of muscular rigidity over the abdomen may enable us to exclude perforation. In perforating gastric ulcer, the greatest pain and tenderness may be in the appendiceal region. This is due to the peculiar conformation of the transverse mesocolon in the region of the pylorus by which the extravasated fluid is directed toward the right renal pouch, thence into the right iliac fossa. Such symptoms appeared in 18 out of 49 reported cases. It should not be forgot that perforation may be multiple. A large number of recorded cases shows that more than one opening was present in 20% of the cases. [A.B.C.]

Penetrating Abdominal Wounds.—H. Gebele's² observations have convinced him that during times of peace all penetrating wounds, whether stab or shot wounds, should be treated with laparotomy. During war immediate laparotomy is always indicated, when hemorrhage exists; unless there is hemorrhage gastrointestinal wounds can wait safely, if protected by an antiseptic dressing. [E.L.]

Popliteal Aneurysm in a Boy.—This case is reported by J. F. Black³ because of the great rarity of aneurysm in the young. The patient was a boy of 9 with a previous history of measles and diphtheria but no family history of syphilis. The aneurysm was of the sacculated variety and arose from the posterior wall of the artery. It was the size of a large walnut, and was removed after ligation of the vessel above and below. Perfect use of the limb was recovered. [A.G.E.]

The Evolution of Abdominal Surgery from Observations Extending Over a Third of a Century, and Founded on Over 2,000 Operations Performed.—A. W. Mayo Robson's⁴ address abounds in numerous interesting statements and in many instructive comparative statistics. He gives a general review of the evolution of surgery during the past 30 years, presenting some hopeful views for the future. He states it is reasonable to hope that before another decade has passed, cancer will have been hunted to its source,

and a means of cure discovered. When we have seen what preventive measures have done for rabies, leprosy, etc., is it too much to hope for the extinction, by repressive legislation, of syphilis or many diseases due to the gonococci? The next generation will probably see tuberculosis in all its forms becoming a rare disease. In the future it seems reasonably sure that the diseases produced by the normal colon bacillus, such as appendicitis, cholecystitis, colitis, cystitis, pyelitis, peritonitis, etc., will be dealt with by the method of immunization in many instances, and diseases induced by the pus organisms will be more generally treated by antistreptococcus serum. Concerning the diagnosis of various diseases of the human body, the services of the skilled pathologist will be more and more called into requisition. The surgeon, the bacteriologist, the pathologist, and the internist will work more and more in harmony. The address is interesting and instructive. [A.B.C.]

TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

REVIEW OF LITERATURE

Stammering Treated by Hypnotism.—G. Hudson Maquen¹ recently demonstrated on a boy of 14 a method which he has found of considerable value in treating certain cases of stammering. The method is that of inducing the lighter stages of hypnotism, and then suggesting to the patient that he can talk. The value of this procedure lies in the fact that the stammerer is usually suspicious and incredulous in the waking state, and will not believe what is told him regarding his capabilities of speech. When he is hypnotized he is told that he will not and cannot stammer if he follows out the directions that are given him at that time, and also those that are given while he is awake. In some cases of the so-called mental stammering, results which seemed impossible by any other method have been attained by this treatment. Hypnotism is not recommended as a cure for stammering, but only as a means of inducing in the patient the necessary condition of mental receptivity for the regular physiologic training. [A.G.E.] [Nevertheless, it would be far better to depend upon normal suggestion. Dercum has shown that the hypnotic state is one of "artificially induced hysteria," and therefore to be avoided. S.S.C.]

Escoquinin.—Dommer² describes the results of the use of a new form of quinin, made by combining a glucosid found in the horse-chestnut with quinin. The resulting salt, to which has been given the name escoquinin, is an amorphous yellow powder, almost insoluble in water and ether, but freely soluble in alcohol, and possessing a bitter taste. It is given in doses of 0.1 gm. to 0.2 gm. (1 gr. to 3 gr.), preferably in capsules. Dommer states that it is useful especially as an analgesic in neuralgia, migraine, rheumatism, and the like. [H.C.W.]

Diabetes Insipidus.—A. Wolff³ reports on 2 patients with diabetes insipidus, treated with secale cornutum; one was under this treatment for months; his quantity of urine diminished from 11,000 cc. to 2,000 cc., his thirst disappeared after the first dose, and he gained several pounds in weight; his general health improved very much. The second patient derived less benefit. In Wolff's opinion the drug acted by contracting the bloodvessels, thus diminishing the quantity of blood, which passed through the kidney. The primary cause of the disease probably rests on a functional change in the renal epithelium; at least in diabetes insipidus, the point of urinary concentration is much lower than normal: 0.22°-0.33° instead of 1°-2.7°, the blood falling little below the normal point, however. [E.L.]

Dormiol.—Dormiol is dimethylethylcarbinolchloral. It is a colorless liquid, having a penetrating odor, resembling that of menthol and of camphor, a cool taste and yet burning. According to Combemale⁴ it may be used in place of the other hypnotics in certain cases of rebellious insomnia as it produces no disorder of circulation or respiration, but induces calm

¹ Lancet, August 29, 1903.

⁴ Journal des Praticiens, Vol. xvii, No. 32, 1903, p. 504.

sleep undisturbed by unpleasant dreams. Dormiol is prescribed in the dose of from 1 gm. to 4 gm. (15 gr. to 60 gr.) in solution in water to which a little syrup may be added. The drug may also be given in capsules. Combemale has seen sleep follow the administration of a single capsule containing .45 gm. (7 gr.) in some cases of asthma and cardiac disease. [L.F.A.]

Euquinin in the Treatment of Malaria.—DeCarlo¹ has obtained good results with euquinin in malaria, especially in children in whom the absence of the excessively bitter taste of the ordinary drug made it easy of administration. Even prolonged use of large doses failed to produce any digestive disturbances. [H.C.W.]

OPHTHALMOLOGY

WALTER L. PYLE

EDITORIAL COMMENT

The Present Status of Subconjunctival Injections.—Since the introduction of subconjunctival injections 7 or 8 years ago, a great amount of literature has appeared regarding their merits. As is usual in the case of a new method of treatment, the most extravagant claims have been made as to the extent of its usefulness. On the other hand, as many of the most hopeful predictions have failed of fulfillment, considerable skepticism has developed as to its value in ophthalmic therapeutics. A careful study of the relative literature since 1897, made by C. S. Bull,² shows how contradictory has been the evidence offered, although as a whole it is sufficient to give the method a permanent place in ophthalmology. Bull states that a study of the reported cases leads irresistibly to at least one conclusion, viz.: That the efficiency of these various solutions injected beneath the ocular conjunctiva cannot be ascribed to the increased local acceleration of the lymph currents, the so-called leukocytosis, nor to the antiseptic action of the remedies employed, since the presence of such processes cannot be demonstrated in the tissues of the eye, following the injections. The chief change seems to be in the composition of the aqueous humor, which becomes richer in albuminoids, due to irritation of the bloodvessels. It is likely that coincidental with this increase of serum albumin in the aqueous is the appearance of various protective substances of the blood, which physiologic chemists have taught us are always found in combination with the albuminoids of the blood. During the past 3 years Bull has employed subconjunctival injections of sodium chlorid, sublimate, mercuric oxyeyanid, and hetol (sodium cinnamate) in solutions of varying strengths. The diseases so treated included different forms of keratitis, choroiditis, iridochoroiditis, detachment of the retina, cellulitis of the lids and orbit, and panophthalmitis. He has not been able to determine any important difference in mode of action or effect between salt solutions and solutions of mercuric cyanid, except that the latter are infinitely more painful, even when combined with cocain or acocin. With the exception of

some brilliant results in several cases of orbital cellulitis of an infectious character, Bull has seen no reason to believe that subconjunctival injections of any of the solutions commonly used bring about any more rapid or favorable results than other methods of treatment hitherto employed for affections of the cornea, uveal tract or retina. His conclusions, based on observations of his own cases and a careful study of the literature of the subject, are that all reports of the beneficial effects of subconjunctival injections should be carefully criticised and compared with the results obtained by other and less troublesome methods of treatment, before accepting them as of any real value.

Suggestions for the Blind.—With the characteristic energy of a true scientist, Javal, the wellknown French oculist, who became totally blind nearly three years ago, has recently devoted his time to collecting suggestions relative to the lessening of the disability due to the onset of blindness in adult life. These with his own valuable experiences he presented to *Société Française d'Ophthalmologie* last year, and a more extensive work on this subject is expected to follow. The author invites communication of further suggestions or experiences. His address is E. Javal, 5 Boulevard Latour-Manbourg, Paris. After citing numerous wellknown examples of persons whose useful activities were not curtailed by blindness coming on in adult life, Javal first addresses himself to those who have the care of the blind. In hopeless cases, he deprecates a mistaken sense of humanity in holding out false hopes, by medication, electricity, etc. He believes that as soon as the oculist is certain that blindness is inevitable, he should urge the patient to use the little sight left to prepare himself for total blindness. Javal contends that the loss of one sense does not lead to further development of the others, but that the afflicted person learns to notice sensory impressions that others overlook, and to interpret them with increasing skill. In illustration he cites his keen judgment of the chief characteristics of a stranger by the feel of the hand and sound of the voice. Touch and hearing are the blind man's chief sources of information as to his surroundings, and their value and cultivation is discussed and illustrated by personal experiences. He advises frequent visits to high-class theaters to develop the judgment of emotion by the sound of the voice. A light cane is called the blind man's antenna, and its numerous uses are described. Attention is called to the remarkable sense of obstacles possessed by the blind, and in explanation it is suggested that it may be in some way associated with the ultraviolet and ultrared rays, which though invisible to the human eye have certain effects on the skin. Instructions for orderly and invariable arrangement of household furniture, books, etc., are given, and many valuable details in domestic life, particularly with regard to eating, drinking, bathing, etc., are discussed. By means of the Braille raised letters, relief maps, sketches and plans, writing boards, typewriters, and phonographs, much useful diversion is offered to the blind man of scholastic inclination. Javal encourages walking, but advocates the use of some sign such as dark glasses, or the cane, to indicate the infirmity, rather than vain attempts to conceal it. Javal himself has derived great pleasure from the use of a tandem tricycle in company with a trusted companion. With a good memory a blind man may become expert in playing dominoes, chess, draughts and card games. Special boards, characters and playing-cards for the blind may be obtained in nearly every large city. A curious comment is that on tobacco-smoking Javal says that it is a mistake to suppose that the blind get no enjoyment from smoking, at least, those who have smoked before the loss of sight. That the cigar or pipe has gone out may not be recognized by the blind so quickly, he acknowledges, and says, that when in doubt he surrounds his cigar with his hand to feel the heat. Very dry cigars

¹ Die Med. Woch., 1903, 4, 375.

² Trans. American Ophthal. Society, 1903, p. 81.

are best as they may be smoked slowly and do not go out.

The Use of X-rays in Ophthalmology.—The invaluable aid of skiagraphy in the treatment of foreign bodies in the eye is universally recognized, and the salient points in localization are now incorporated in modern ophthalmic teaching. Recently the therapeutic virtues of these rays have been extensively utilized in ophthalmic practice. Numerous cases of successful treatment of rodent ulcer of the eyelids have been reported. The eyelids, especially the lower, are a common site for rodent ulcer, and, as elsewhere, application of the x-rays may bring about a cure. M. S. Mayou¹ holds that the x-rays act by producing a local leukocytosis. The leukocytes remove all irritating cells or substances, or encapsulate them and prevent their spread. The cure of tuberculous of the conjunctiva by the x-rays has been reported by Sydney Stephenson,² and the same author and David Walsh say that the x-ray and high-frequency electric currents are of great value in the treatment of trachoma. At a recent meeting of the Ophthalmologic Society of the United Kingdom, M. S. Mayou reported an extensive experience in the treatment of trachoma by x-rays. At the present time trachoma is treated by applying some form of irritant, either chemic or mechanical, to the eyelid, producing a leukocytosis. In the x-rays we have a method of setting up a leukocytosis with the absolute minimum of destruction to epithelial and other tissues. In this way excessive scar formation is avoided. Further, the effect produced from a slight leukocytosis to actual gangrene, is under almost perfect control. There is much less deformity in the lid after treatment, the procedure is practically painless, and pannus clears up quickly and thoroughly. Mayou found that even prolonged exposure of the globe to the x-rays was attended only by such trifling bad results as falling out of the lashes and conjunctivitis. Experiments on rabbits and frogs showed that the x-rays did not bleach the visual purple. The results of treatment by the x-rays are compared by Mayou with those produced by copper sulfate, jequirity, and other irritants, and it is pointed out that there is less destruction of tissue and subsequent cicatrization, as well as less pain, with the former method. In applying the rays the eyelids are everted (the operator's hands being protected by bismuth ointment and cotton gloves) (the cornea is only exposed in severe cases where pannus was present). Owing to the infiltration set up, difficulty was found in deciding when that treatment should cease. Out of nine cases, five remained well, one cleared up but recurred two months later, two others improved and were still under treatment, and in one case of corneal opacities following trachoma the vision had improved from perception of light to counting fingers at three feet. The disadvantages of the treatment were: (1) All patients did not react well to the x-rays, and (2) it was sometimes difficult to tell when treatment should cease.

Test-characters for Children and Illiterates.—To avoid the difficulties met in using the ordinary illiterate test-cards of Snellen, Burchardt Boettcher, Guillery, Galezowski, Lotz, Wolffberg, de Wecker, Albrand, Praun, Heiman, and others, Dr. Arthur E. Ewing, of St. Louis, has recently published an admirable set of universal test-characters. The characters used are a cross, a horse-shoe, a square, a circle, a star, and in profile a mug, a pitcher, a teapot, and two chairs. All are drawn approximately to Snellen's scale of 1' visual angle for the thickness of the line and 5' for the size of the object, but with variations necessitated by the forms of certain objects, as the two chairs, the cross and the teapot. The differences in the ease of recognition of the several characters are found to be not much, if at all, greater than

in the case of the standard test-letters of Snellen. An intelligent child will often name these characters, or at least a sufficient number of them, correctly at first sight, perhaps calling the square a "box," or a "window," or a "picture frame;" the circle a "hoop," or a "ring," etc. In most cases, however, some study of the characters is found to be necessary, and for this purpose Dr. Ewing has had them printed singly on small cards, and gives them to the child to look at and to learn to name them at home.

The graduations in size and the numbering of the several sizes of the characters are the same as in Dr. John Green's "Test-letters in Geometrical Progression," communicated to the American Ophthalmological Society in 1867, and strongly recommended as the standard by Javal. The ratio, as compared with the next larger size, is $\sqrt{0.5}$ ($= 1 : 0.707$, or practically $1 : 0.7$), or, as compared with the next smaller size, $\sqrt{2}$ ($= 1 : 1.414$, or practically $1 : 1.4$), which gives the convenient series: —5, 7, 10, 14, 20, 28, 40, 56, etc., the successive numerals representing the distances at which the several sizes of characters should be discerned by a person of normal vision.

REVIEW OF LITERATURE

The Operative Treatment of Myopia.—Frost¹ considers the question of operation on the second eye after a successful result in the first. His view at present is that unless there are some exceptional circumstances it is better left alone. The main object of the operation is to render the patient independent of glasses. The eye that remains myopic can see near objects unaided, while the other serves for distant vision. The possibility of obtaining binocular vision is, of course, too remote to be worth considering. He has only operated on both eyes in 2 cases, and in 1 the presence of lamellar cataract was the reason. In the other, the second operation was undertaken at the patient's request, and glasses would have been required in any case to correct the astigmatism. Although well satisfied with the improvement produced in distant vision by the operation in suitable cases, he has several times been disappointed in the power of near vision, some of the patients having been unable, with any correction, to read small print. Possibly this is due to their having acquired a habit of reading with the other eye. In 1 of Frost's cases, a man of 21, glaucoma supervened. Suppuration occurred in 2 cases, both children. Detachment of the retina followed after 6 operations, in 1 case after 3½ years of excellent vision. From a study of his 31 cases (33 eyes), Frost concludes: 1. The operation should be restricted to patients whose actual myopia is not less than 12 D. (that is, who require a correcting lens of not less than 13.5 D.). 2. The patient should be able to read 1 J without glasses with each eye. 3. After the entire removal of the lens, the distant vision *without glasses* is usually at least as good as it was before *with glasses*, and with correction it is usually much better. 4. The operation should be limited to the more myopic eye, except under special circumstances.

Euphthalmin as a Mydriatic.—Hale² repeats his former enthusiastic endorsement of euphthalmin as a safe and convenient mydriatic for diagnostic purposes. He concludes: 1. Euphthalmin (5% to 10% watery solution) produces practically no subjective symptoms. 2. Its mydriasis is of short duration. 3. The effect shows itself earlier in youth than in age. 4. It does not noticeably influence tension. 5. It has no effect on conjunctiva or cornea. 6. It influences accommodation to only a slight degree. 7. The normal condition of the pupil is rapidly restored. 8. It is apparently nontoxic. Hale has used euphthalmin for 3 years in all kinds of cases, old and young, for diagnostic purposes. He finds that he obtains a satisfactory dilation in nearly every instance after 2 drops at five-minute intervals at the end of 45 minutes at most, using either a 5% or 10% solution. This dilation lasts usually 2 hours, never more than 4 hours, and causes no inconvenience to the patient beyond the unusual amount of light. Although there have been reports of increased tension as well as a true glaucomatous

¹ Lancet, February 29, 1903.

² British Medical Journal, June 6, 1903.

¹ Ophthalmoscope, July, 1903.

² Medicine, 1903, p. 532.

attack induced by euphthalmia, Hale has seen no tendency to increase of tension from its use.

The Conservation of Binocular Single Vision.—In an extensive article on this subject E. R. Lewis¹ offers the following conclusions: 1. The only congenital attribute of vision is proper light-perception. All other visual attributes depend upon learning on the part of the child. 2. In many cases certain influences cause this learning to be directed into other than normal paths, in which event the act of binocular single vision is not learned. 3. Lack of binocular single vision is a very prevalent condition. 4. This lack represents great loss to the individual. 5. Cases in which the casual influences can be removed may be differentiated from those in which such removal is impossible. 6. Proper measures adopted at the right time will result in conservation of binocular single vision in a large number of cases.

Myopia in Diabetes Mellitus.—Neuburger² records 2 cases in which the sudden development of myopia led to the discovery of diabetes mellitus. Hirschberg was the first to demonstrate that myopia may develop in the course of diabetes mellitus in eyes previously emmetropic or hypermetropic without turgidity or opacity of the lens. The explanation usually given that the myopic change is due to the altered refractive index of the lens-substance induced by the glycosuric state, is not very convincing, as the myopia may disappear abruptly and the diabetic changes elsewhere increase. Neuburger makes a plea for a careful examination for glycosuria in all cases of myopia beginning in middle life.

Embolism of the Central Artery of the Retina Following Paraffin Injection into the Nose.—Hurd and Holden³ report a case of this nature in a man of 32. The case is the most recent addition to the list of unfortunate results following paraffin injections. A study of the retinal changes was made almost from the time of formation of a true embolism of the central artery, and demonstrated that the plugging of the retinal arteries was due chiefly to endarteritis obliterans instead of an embolism. The only similar case of blindness on record is that reported by Leiser.⁴

Operation for Detachment of Retina.—Müller⁵ aims to prevent choroidal tension and retinal dislocation and stretching by the excision of a piece of sclera (in size about 8 mm. by 20 mm.) from the external portion of the posterior segment. The choroid is left intact, and precautions are taken not to allow more of the subretinal fluid to escape than is required by the diminished size of the globe. Müller has performed this operation with successful results in 7 patients.

Potassium Permanganate in the Treatment of Purulent Ophthalmia.—In cases of purulent ophthalmia, Vian⁶ cauterizes the palpebral conjunctiva twice daily with a 10% solution of potassium permanganate used on absorbent wool rolled about a wooden or metal applicator. Irrigations with boric acid are used, and as the suppuration diminishes, the permanganate is applied less frequently. In 53 cases so treated (7 in adults) the results were uniformly successful. The advantages claimed are rapidity of cure, harmlessness particularly to the cornea, and relative painlessness. Vian claims that when used in cases of diphtheric conjunctivitis these applications do not aggravate the condition like those of silver nitrate.

Skin-grafting for Restoration of the Eyelids.—Dodd⁷ advises that for the upper lid, Thiersch grafts should always be used, unless the whole thickness of the lid is destroyed. In forming the lower lid, if there is adjacent skin available, it should be used to form the lid and the resulting defect filled in with Thiersch grafts. When there is dense cicatricial tissue for the floor of the graft a pedicle graft is the only one which I have found satisfactory. Should pedicle grafts not be available and the underlying tissue have proper vascularity, then either Wolfe or Thiersch grafts may be used, and his results have been best with a Wolfe graft prepared very thin.

Double Iritis following Mumps.—Collomb¹ reports a case of this nature in a young man of 29. The right eye was attacked simultaneously with the swelling of the parotid glands and a marked posterior synechia was the result. A subacute iritis of the left eye followed a month later, with resultant synechia, that could not be broken by vigorous atropin instillations.

A Modified Glass Ball for Use in Mules' Operation.—Bronner² recommends a Mules' ball with a hole in the middle, which is covered in with glass so as to keep out air and water. He operates as follows: A catgut suture is passed through and tied on to each of the tendons of the 4 recti muscles. The eye is then removed. The glass ball is introduced into Tenon's capsule, a thick silk suture is passed through the center with a needle attached to either end. The superior and inferior, also the external and internal recti muscles, are then tied together over the ball. Three or four catgut sutures are put through the subconjunctival tissue above, below, and over the ball, and tied together in a vertical line. The needles attached to the end of the silk suture of the glass ball are passed through either side of the subconjunctival tissue. Four sutures are then put through the conjunctiva on either side and over the ball, and united in a horizontal line. The ends of the suture of the glass ball are not covered in by the conjunctiva, but are allowed to hang out at the outer and inner ends of the line of suture. They are then loosely tied together over the sutures so as to keep the glass ball *in situ*. The silk suture is not removed for 5 or 11 weeks, so as to give the parts time to become thoroughly organized and hardened.

Metastatic Carcinoma of the Choroid.—Oatman³ reports a case of this nature, and makes a very comprehensive review of 30 cases on record of which he considers the reports trustworthy. He has compiled the following table of differential diagnosis:

CARCINOMA OF THE CHOROID.	SARCOMA OF THE CHOROID.
Always secondary.	"Secondary sarcoma of the choroid is unknown." (Fuchs.)
Has always occurred posteriorly, usually on the temporal side of the nerve.	May occur at any point.
A flat discoid tumor or thickening of the choroid which spreads laterally.	A rounded protuberance growing out into the vitreous.
Early detachment of the retina.	Late detachment when centrally located. (Griffith.)
Destroys vision in a few weeks.	May exist a long time with good vision.
Has not been described as being vascular.	May appear vascular.
May be very painful with T. N. or T-.	Pain is due to +T.
First symptom may be a rapid increase of hypermetropia without marked ophthalmoscopic changes.	Too circumscribed to produce hypermetropia.
T. may be diminished.	If confined to the choroid T. is never diminished. (Marshall.)

The Treatment of Myopia.—R. Liebreich⁴ has made a special study of skulls of cadavers and living individuals, and has observed a physiologic asymmetry of the orbits and the halves of the face. This he found to be due to variations in the shape of the malar bone. This asymmetry affects only the outer halves of the orbit, and those which affect also the upper jaw, frontal and temporal bones, he considers pathologic. The inner halves of the orbit are usually symmetric. As the distance of the optic foramina from each other, and the distance of the turning point of the eye from the internal orbital surface, and the depths of the orbits measured along the internal surface are almost constant in the greatest variety of skulls, the size of the angle formed by these vertical lines may be determined by the breadth of the nose, when examining a skull, by the distance of the pupils from each other in the living individual. This angle determines the development of myopia, as

well as its heredity. If it is too large, the internal recti are made to exert themselves out of proportion; the accommodative power is strained, and in time myopia is produced. The use of prisms he considers the only positive remedy against the progress of the disease. In extreme cases he combines these with very weak concave glasses. [E.L.]

Hereditary Optic Atrophy.—C. L. Mix,¹ after stating that this condition is transmitted through unaffected females, says he is almost ready to formulate a law that in the evolution of an individual variation inheritance is invariably through the female, who is herself unaffected. This statement is based on the law regarding the condition in question, and which is the same in hemophilia, Daltonism, hemeralopia, Friedreich's hereditary ataxia, and other parallels. The etiology of hereditary optic atrophy is obscure. At best we can only assume an imperfectly endowed visual apparatus which early undergoes involution, just as does the brain in cases of dementia precox. The cases reported by Mix are eight in number, from one family. The time of onset was within the narrow limits of 18 to 25 years or 22 to 25 for seven of the eight. The history extends through six generations, and in four of them cases have appeared. There are living at present four representatives all amaurotic, three brothers and a nephew. An uncle of the three brothers was also temporarily affected, as shown by the family tree that accompanies the article. The four living cases show nothing not hitherto reported except one brother, who has ataxic paraplegia. [A.G.E.]

Leukemic Retinitis.—Retinal changes in leukemia have been often studied but some points still remain unexplained. K. C. Orloff² describes the histologic findings in the retina of a man who died from leukemia. The most notable feature was the distribution of the wellknown tumor-like formations along the course of the vessels. This observation is not in accord with most authorities who maintain that these little "tumors" can form at any point of the retina. Of course, simple hemorrhages into the retina may occur, but they will give a different picture; moreover, in the case reported such hemorrhages were absent. [L.J.]

Curative Treatment of Trachoma by Röntgen Ray Tube Exposure and by High Frequency Current.—S. Stephenson and D. Walsh³ use the expression "focus tube" exposure since it is not known whether the Röntgen rays themselves are the sole or even the chief therapeutic agents. Only one case so treated has been previously recorded in literature. The present writers report the results in four, in all of which there was marked improvement, two being cured and the others promising cure with continuance of the treatment. These results obtained by a few weeks' treatment open up a new era as regards trachoma. The clearing up of corneal opacities and partial disappearance of pannus suggests important extensions of the method. Results in the case in which the high frequency current was applied were not less striking. Both methods are painless. In unskilled hands the focus-tube might play havoc with the eye. [H.M.]

Treatment of Tuberculosis of the Iris with Tuberculin T.R.—M. Handmann⁴ reports the cases of 2 individuals afflicted with tuberculosis of the iris; one had the disease in both eyes. Under the use of tuberculin the small nodules existing along the outer part of the iris disappeared, and very satisfactory visual power returned. The cases were observed for 18 months without recurrence. While the possibility of a mistaken diagnosis and spontaneous recovery must be considered, the very fact that the carefully administered tuberculin did not produce any deleterious symptoms, should be sufficient to treat other similar cases with the drug also. [E.L.]

Conjunctivitis due to Fast Driving.—A. E. Davis⁵ states that the conjunctivitis caused by rapid riding in open automobiles with the eyes unprotected has several points of difference, particularly in the chronic stage, from ordinary conjunctivitis. These points are: (1) the inflammation is confined almost wholly to the bulbar or ocular conjunctiva; (2) the deeper con-

junctival and subconjunctival vessels are enlarged and tortuous, especially noteworthy being the number of the deeper vessels affected; (3) there is a clearer and more watery discharge than in the ordinary forms. Treatment consists in removing the cause and in the application of cold compresses to the eyes for 15 minutes at a time, three or four times a day, and the application of mild astringent washes twice daily. Davis protests strongly against the indiscriminate use of adrenalin chlorid solution which is frequently prescribed in these cases. The continued over-stimulation of the muscle fibers of the vessels leads finally to a passive congestion more difficult to control than is the original condition. The use of this drug is positively harmful in these cases. In fact, it is of only small remedial value in any disease of mucous membranes and its local use should be limited to that of a styptic in operations on these membranes. [A.G.E.]

Miliary Tuberculosis of the Choroid.—This condition is a valuable sign of general miliary tuberculosis. Choroidal tubercles are from $\frac{1}{2}$ to $\frac{3}{4}$ the diameter of the optic disc, are usually spheric, although the larger ones may be ovoidal, and are pinkish-yellow to yellowish-white in color. Their most constant characteristic is their projection into the retina. E. Margulies¹ in this paper reports the only case on record in which this projection was absent. This exception to the rule is accounted for by the fact that the tubercles in this case had their origin in the deeper parts of the choroid. [B.K.]

Tuberculosis of the Conjunctiva Cured by the Röntgen Rays.—Sidney Stephenson² reports the case. Patient was a child 4 years of age. The diagnosis of tuberculosis of the conjunctiva was positive from microscopic and cultural examinations. Treatment by the Röntgen rays was instituted and cure was effected without any visible cicatrization except such as was produced by the excision of the material for diagnosis. The treatment by Röntgen rays is simple, painless and free from danger. He is of the opinion that to judge by a single case, this method is likely in the future to displace the other methods of treating tuberculosis of the conjunctiva. It is to be remembered that spontaneous cure of tuberculosis of the conjunctiva may rarely occur. This occurs so seldom that treatment by any means which will promise a cure is to be recommended, and in the present light of our knowledge the Röntgen rays are best. [A.B.C.]

Trachoma.—A. Peters³ warns against making a diagnosis of trachoma only in cases where true trachoma granules and scars are noted. The trachoma granule is nothing more than a reaction of the normal tissue to the presence of adenoid tissue and the scar formation depends upon the existence of these adenoid follicles. In some cases instead of adenoid tissue development we have nothing more than chronic, dry conjunctivitis, a form of slight trachomatous infection. Such abortive forms are quite dangerous, as they are usually overlooked and may often by producing new infections lead to serious consequences. He relates several such instances. An efficient prophylaxis is almost impossible, but the best preventive is probably the removal of all adenoid tissue in the very earliest cases, and to effect this all trachoma regions should be searched most thoroughly for their true and abortive cases. Bacteriologically considered, the disease is usually a mixed infection. [E.L.]

Phlyctenular Ophthalmia in the White and Black Races.—H. D. Bruns⁴ says he is aware of no study of the relative liability of the white and the negro to attacks of this affection nor has any one called attention to the greater severity of the malady and its curious varieties in the latter race. Of 17,311 eye cases in his clinic, 5,052 were cases of conjunctival disease. Of these, 2,002 were colored and 39% were phlyctenular cases. Of 3,050 whites only 14% were phlyctenular cases. The period of life over which liability to attack extends is longer in the negro than in the white. The disease is much more severe in the negro, many of the cases being almost hopeless. Bruns gives tables showing the effect of local treatment with mercurials alone, mercurials with other agents, and without mercurials. He interprets them as showing that local

treatment has but little to do with the progress of the case, [A.G.E.]

Primary Sarcoma of the Iris.—Henri Coppez and Jean de Vaulcroix¹ report such a case occurring in a woman 45 years old. A black tumor had developed in the anterior chamber of the right eye during the 4 or 5 years preceding her first visit to the hospital. The tumor occupied the external part of the iris, extending on one side almost to the pupillary margin, and on the other to the iridocorneal angle. There were also 3 or 4 black spots, irregular in outline, in the other parts of the iris. The tumor did not extend to the posterior parts of the eyeball. The other eye was normal. The tumor was removed, but 9 months later it became necessary to enucleate the eyeball, as sarcomatous nodules had developed. The tumor proved to be a spindle-celled sarcoma, and an examination of the eyeball showed that the process was both extraocular and intraocular. The case demonstrates the danger of penetrating eyes, which are the seat of malignant growths. The author concludes that enucleation is preferable to excision of the tumor in cases of sarcoma for 3 reasons, namely: (1) The opening of the sarcomatous eye is dangerous from the point of view of local or general recurrence; (2) the suprachoroid region is frequently affected from the beginning; (3) there can exist under the iris metastatic foci resembling in appearance congenital pigmentation. [J.H.W.R.]

Clinical and Pathologic Examination of Intoxication Amblyopia.—The patient, a man of 35, who had always used tobacco and alcohol excessively, lost his eye 7 years before his death due to an injury with hot iron. His right eye continued to be good until 9 weeks before death, since when he noticed a gradual diminution of vision. Examination showed a central relative scotoma for white and all colors of about 10 degrees. Vision = 0.3. Papillary border slightly hazy, but no pallor of the temporal half of papilla. He developed delirium tremens, jumped out of window, and died as the result of his injuries. The autopsy was performed 16 hours afterward, thus excluding the possibilities of examining the retina according to the Nissl method. The optic nerves of both sides, but especially on the left, showed in the papillomacular bundles increase of the interstitial connective tissue, formation of new bloodvessels, capillary endarteritis obliterans, spaces in the nerve substance into which the connective tissue was growing, without, however, compressing the nerve fibers. After studying this case thoroughly, F. Schieck² cannot agree with Birch-Hirschfeld, who sees in such amblyopias a lesion of the retinal ganglia, but concludes that the process begins in the optic nerve as an endarteritis obliterans. The macular fibers, being centrally located, suffer in their nutrition and a scotoma is thus produced. [E.L.]

Variations in the Technic of Cataract Extraction.—Captain R. H. Elliot,³ of Madras, who recently visited the principal eye-hospitals in Italy, Switzerland, Austria, Germany, Belgium, Holland, Poland, Russia, Denmark, Sweden, and France, says that the point most impressed upon him was the variety of method employed by different surgeons to obtain the same end. This was nowhere more obvious than in cataract extraction, that operation being the text for his very instructive paper. The stages of the operation dealt with are preparatory measures, preparation of the patient, the operation, the question of iridectomy, removal of the lens, and methods of bandaging. Each of these points is considered at length, the technic of the various operators being described. The article must be read in full to be appreciated. [A.G.E.]

Copper Citrate in Ophthalmology.—Copper citrate is a green, odorless and tasteless powder, easily soluble in water. It possesses certain bactericidal properties. Recently the salt has been recommended in the treatment of trachoma. A. G. Crotow⁴ gave the remedy a trial in 109 cases, embracing pannus tennisi, pannus crassus, granular trachoma, chronic conjunctivitis, and corneal maculas. The remedy was applied in several ways: As a powder of 5% to 10% strength with sugar as a base; as a 5% to 20% ointment in vaselin, or lanolin, or glycerin; in

the form of sticks containing 10% to 20% copper citrate, and in saturated aqueous solution as a lotion. The best results were seen in pannus tennisi from the use of the 5% to 20% glycerin salve. Secretion was rapidly arrested and vision improved in a short time. Excellent effects also followed the use of this ointment in corneal maculas. In recent trachoma the copper citrate pencil acted well. Chronic conjunctivitis, on the other hand, did not yield to the new remedy, which, nevertheless, deserves all attention as unrivalled in pannus and corneal maculas. [L.J.]

Contracture of the Sphincter of the Iris in Accommodation and Convergence of Pupils not Reacting to Light.—M. Rothmann¹ reviews all the cases reported to have this peculiar symptom and gives the details of one coming under his own observation. During the course of an attack of migraine a girl of 12 was suddenly found to have isolated paralysis of the sphincter of the right iris, with extreme dilation of the pupil. Partial reaction to accommodation and convergence returned shortly but never to light. The pupil would remain contracted for 1 minute, and then needed 1½ minutes, to return to complete dilation. The paralysis he believes to be due to a small central hemorrhage; the limited return of power to a contracture of the iridal sphincter. [E.L.]

Sarcoma of the Choroid in a Child.—W. E. Bruner² reports a case of sarcoma of the choroid, of about 2 years' duration, in a child of 6 years. Several physicians and oculists had advised against operation. Metastases appeared soon after complete exenteration was performed and death occurred in 4 months. The case had at first been diagnosed as subsiding panophthalmitis and subsequently as glioma. The age of the patient was that at which glioma, rather than sarcoma, usually appears. [A.G.E.]

The Projection of the Retina upon the Cortical Calcarine.—S. E. Henschen³ believes that there exists without doubt a central retina in the cortical "calcarine." He states that in medical literature there does not exist a single fact that is in opposition to his conclusions. The whole lateral surface of the occipital lobes can be destroyed without causing any disturbance of vision. Lesions of the cortical "calcarine" alone cause hemianopsia. He reports a case in which the lesion was limited exactly to the cortical "calcarine," and shows diagrams which go to prove that the lesion in the optic radiation is of a secondary nature. There exists in this case an exact hemianopsia. In a second case the cortical "calcarine" was destroyed, the lesion attacking only the medullary substance near the occipital lobe. The lateral surface of the opposite hemisphere was destroyed over a great extent. The second lesion did not provoke hemianopsia; this only existed in the right visual field. He quotes, with illustrations, a number of other cases which seem to demonstrate the existence of hemianopses a quadrant, and that the fibers from the superior calcarine lip supply the superior part of the retina, the inferior calcarine lip corresponding to the inferior part of the retina. [J.H.W.R.]

Peribulbar Carcinoma.—W. Reis⁴ reports in a man of 72 a case of peribulbar carcinoma, taking its origin from the epithelium of the connective tissue at the corneoscleral junction. The tumor grew rapidly and showed a marked tendency to fatty and other degenerations. It surrounded almost the entire eyeball at the time of its removal. The bulb was not invaded at any point by the cancer tissue, nor were there metastases in the interior of the eye. The eyeball presented the picture of a total atrophy due to the pressure of the tumor masses and the inflammatory reaction. The nasal part of the eyelid was slightly implicated. [E.L.]

A Case of Streptococcus Conjunctivitis with a Subsequent Panophthalmitis and a Fatal Termination.—After briefly referring to similar observations in literature, Engels⁵ reports the case of a male child 1½ years old, who 4 days after an attack of measles, developed redness and swelling of the lids of the left eye. Two days later the right eye also became affected. There was a diffuse bronchitis with beginning bron-

⁵ Hyg. Rundschau, June 1, 1903.

chopneumonia of the right lung. At the first examination, the left cornea perforated and the lens escaped. The swelling and redness of the lids continued to increase, and the right-sided corneal ulcer spread until it involved nearly the entire cornea. Fever was high, and the child gradually sank and died. Bacteriologic examination revealed in the right eye only streptococci; in the left, a diplococcus (not that of Fraenkel), producing a yellow pigment, and xerosis bacilli, also forming a yellow pigment. Animal inoculations into the conjunctival sac were unproductive, so long as pure cultures were used; when mixed cultures were employed, the animal died of general infection from the conjunctiva, the cornea presenting a slight degree of turbidity. As goat-serum has been found to destroy the bactericidal complement of rabbits' blood, the author injected rabbits with such serum and then produced the conjunctival infection. The result was a much more severe purulent conjunctivitis. [D.R.]

Localization of Foreign Bodies in the Eye.—L. C. Deane¹ describes his apparatus for localizing foreign bodies in the eye and reports 7 cases to illustrate its use. The localizer is a modification of the machine used by Davidson, of London. Deane also discusses the use of the giant magnet in the removal of pieces of steel from the eye. His own experience does not lead him to fear removing foreign bodies through scleral wounds. In the past 2 years 14 cases have been thus treated without a single detachment of the retina. [A.G.E.]

Ptomain Poisoning with the Result of Hemianopsia.—José G. Mendoza² reports the case. He believes a history of malaria is an influence to be considered. The condition of the eye is given in full; and certain curious symptoms, as exanthem arising in the course of the disease, and later general icterus are detailed. Syphilis is positively excluded. The man, aged 45, a native of Mexico, appears to suffer merely the functional derangement of the retina, and which according to the writer has developed from "Paludism and infection of the nerve tracts or centers" as a result of an autointoxication. [T.H.E.]

The Diagnostic Value of Old Tuberculin in Parenchymatous Keratitis.—Enslin³ has made injections of tuberculin in many cases of parenchymatous keratitis coming under his observation. All of the cases traceable to hereditary syphilis without signs of tuberculosis, gave no reaction whatsoever, with one exception. Here no reason could be found for the reaction, the only feasible explanation being a probable hidden focus. In all the cases where the history pointed to tuberculosis, whether syphilis was present or not, typical reactions were noted; only a general reaction, however, can be said to be of value in these cases. Enslin advises the use of tuberculin injections in all cases in which the slightest doubt exists as to origin of the affliction. [E.L.]

The Visual Fields in Traumatic Hysteria.—Mahillon⁴ looks upon the examination of the visual field, especially for colors, of great importance in posttraumatic nervous troubles. The loss of color perception is in regular order almost always the same, as follows: Violet, green, blue, yellow, and last, red. The persistence of red is characteristic of this dyschromatopsia. When a victim of an accident shows a regular concentric contraction of the fields with reversion of the color fields, together with other nervous symptoms, the case is probably one of traumatic hysteria. The prognosis in these cases must be reserved. The concentric contraction of the color fields cannot be simulated, and any attempts at simulation can be readily thwarted. Medical expert testimony in traumatic cases should be considered incomplete if the precise details of the functional condition of the visual apparatus are not known. When the examination of the visual field is done with care, the weight of such testimony will be great. [J.H.W.R.]

Removal of a Piece of Iron from Lens without Injury to Its Transparency.—O. Feilke⁵ reports the case of a medical student, who presented himself with a piece of iron in his lens 2 mm. long. It had been there for an hour. The corneal wound

was closed and the anterior chamber inviolate. Schloesser's electromagnet took the iron from the lens with ease; it settled in the lower part of the anterior chamber, from which it was removed by a curved Hirschberg magnet through a special incision. Both eyes were kept bandaged for 8 days. Eight months after the injury the vision was almost as good as before the injury. A very slight turbidity in a small part of the anterior portion of the lens could be perceived. [E.L.]

Acute Optic Neuromyelitis.—E. Weill and L. Gallavardin¹ report a case of acute diffuse myelitis with double optic neuritis, occurring in a girl of 14. The clinical history, with autopsy and histologic notes, is given at length. The myelitis was intense in the inferior portion of the dorsal cord. There was slight evidence of peripheral neuritis, involving particularly the sciatic and external popliteal nerves. There was diffuse interstitial encephalitis. A review of the literature reveals only 24 or 25 similar cases. [A.G.E.]

Exophthalmus and Loss of an Eye Through a Blow against the Temple in a Man with Hemorrhagic Diathesis.—B. Pusey² reports the case of a man of 28, who a month before received a blow against the right temple and who ever since presented prominence of the right eye. Examination showed edematous eyelids, exophthalmus, hazy cornea, and normal fundus. V 20/70. Rest in bed, atropin, and a pressure bandage did not improve the exophthalmus, and as the corneal haziness increased it was thought best to explore the posterior part of the orbit. The external rectus muscle was severed and the bulb brought forward; only bloodclots were found, and the wound was closed. The exophthalmus increased, and 2 days later the cornea ruptured. The eyeball was removed 8 days later. The patient bled profusely during the operation and during the first change of dressing. Recovery occurred after several weeks. [E.L.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 2, 1904:

SMALLPOX—UNITED STATES.			Cases	Deaths
Arkansas:	Fort Smith.....	Dec. 12-19.....	1	
California:	San Francisco.....	Dec. 13-20.....	3

Changes in the Medical Corps of the U. S. Army for the week ended January 2, 1904:

MATHEWS, First Lieutenant **GEORGE W.**, assistant surgeon, is granted leave for ten days, from about December 24.

BOURKE, First Lieutenant **JAMES**, assistant surgeon, is assigned to temporary duty as attending surgeon and examiner of recruits in Chicago, Ill.

FISHER, **WILLIAM C.**, contract dental surgeon, is granted leave for seventeen days, from about December 23.

ALLEN, First Lieutenant **JOHN H.**, assistant surgeon, will return from Fort Logan H. Roots to San Francisco, Cal., for duty.

GIBSON, **EDWARD T.**, contract surgeon, now at Fort Ethan Allen, is relieved from further duty in the division of the Philippines, and will proceed to his home, Minneapolis, Minn., for annulment of contract.

PATTERSON, **EDWIN W.**, contract surgeon, is relieved from further duty in the division of the Philippines, and upon the expiration of his present leave will proceed to Fort Washington for duty.

KEMP, **JAMES F.**, contract surgeon, is granted leave for one month.

WATERHOUSE, **M. MANLEY**, contract surgeon, now at Fort Sheridan, will proceed to San Francisco, Cal., for transportation to the Philippine Islands on the transport to sail from San Francisco about January 1.

EBERT, Major **R. G.**, surgeon, is granted leave for one month.

BUSHNELL, Major **GEORGE E.**, surgeon, is detailed to represent the medical department of the Army at the Tuberculosis Exposition to be held in Baltimore, Md., January 25 to 31. Major Bushnell will proceed from the Army General Hospital, Fort Bayard, to Baltimore in time to reach that city on or before January 24, and upon the close of the exposition will return to his proper station.

KULP, Captain **JOHN S.**, assistant surgeon, now on leave in Philadelphia, Pa., is relieved from further duty at Fort McDowell and will assume the duties of attending surgeon and examiner of recruits at Philadelphia on January 1, relieving Captain Charles F. Kieffer, who will proceed to Fort D. A. Russell for duty.

So much of orders of December 23 as directs Captain **Henry R. Stiles**, assistant surgeon, to proceed to San Francisco, Cal., and report by telegraph to the adjutant general of the Army for orders, is revoked.

DESHON, Captain **GEORGE D.**, assistant surgeon, is relieved from duty as attending surgeon and examiner of recruits at Boston, Mass., to take effect February 1, and will then proceed to Fort Des Moines for duty.

HEIZMANN, Colonel **CHARLES L.**, assistant surgeon-general; **BIRMINGHAM**, Major **HENRY P.**, surgeon; and **EDIE**, Major **GUY L.**, surgeon, are appointed a board of officers to meet in Washington, D. C., for the purpose of making recommendations looking to the revision of the Manual for the Medical Department. The board will report to the surgeon-general of the Army for instructions.

WALLES, Major **PHILIP G.**, surgeon, is relieved from duty at Fort Assiniboine and will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands on transport to sail about February 1.

GIBSON, **EDWARD T.**, contract surgeon, leave granted is extended twenty-three days.

McMILLAN, **CLEMENS W.**, contract surgeon, now on leave at Marlin, Tex., is relieved from further duty in the division of the Philippines, and upon expiration of leave will proceed to the Presidio to relieve Contract Dental Surgeon **William G. Hammond**, who will report for transportation to the Philippine Islands.

HARTSOCK, Captain **FREDERICK M.**, assistant surgeon, now in Washington, D. C., will, upon the expiration of his present leave, proceed to Fort Bliss for duty, to relieve Captain **Edwin P. Wolfe**, assistant surgeon. Captain Wolfe will proceed to San Francisco, Cal., for transportation to the Philippine Islands on the transport to sail February 1.

STILES, Captain **HENRY R.**, assistant surgeon, is relieved from duty in the division of the Philippines, and will proceed to San Francisco, Cal., for further orders.

Changes in the Medical Corps of the U. S. Navy for the week ended January 2, 1904:

MARCOUR, **R. O.**, assistant surgeon, detached from the Franklin and ordered to the Dixie, for duty with the Panama Marine Brigade—December 24.

BRISTER, **J. M.**, assistant surgeon, detached from the Isla de Cuba and ordered home—December 24.

GUTHRIE, **J. A.**, passed assistant surgeon, ordered to the Franklin—December 26.

FREEMAN, **G. F.**, passed assistant surgeon, ordered to the Naval Station, Olongapo, P. I.—December 29.

Changes in the Public Health and Marine-Hospital Service for the week ended December 31, 1903:

GEDDINGS, **H. D.**, assistant surgeon-general, to report to Chairman of examining board at Washington, D. C., January 18, 1904, for examination to determine his fitness for promotion to the grade of surgeon—December 30, 1903.

MEAD, **F. W.**, surgeon, granted leave of absence for 1 day, December 28—December 24, 1903.

WHITE, **J. H.**, surgeon, bureau letter granting Surgeon White leave of absence for 5 days from December 17, amended to read 5 days from December 19—December 22, 1903.

MAGRUDER, **G. M.**, surgeon, granted leave of absence for 2 days from December 30—December 28, 1903.

WERTENBAKER, **C. P.**, passed assistant surgeon, to report to Chairman of Examining Board at Washington, D. C., January 18, 1904, for examination to determine his fitness for promotion to the grade of surgeon—December 30, 1903.

PERRY, **J. C.**, passed assistant surgeon, to report to Chairman of Examining Board at Washington, D. C., January 18, 1904, for examination to determine his fitness for promotion to the grade of surgeon—December 30, 1903.

ROSENAU, **M. J.**, passed assistant surgeon, detailed to represent the service at meeting of the Society of American Bacteriologists at Philadelphia, Pa., December 29 and 30—December 24, 1903.

WICKES, **H. W.**, passed assistant surgeon, granted leave of absence for fifteen days from December 24—December 18, 1903.

VON EZZDORF, **R. H.**, passed assistant surgeon, to report to Director of Hygienic Laboratory for temporary duty—December 21, 1903. To proceed to the city of Mexico for special temporary duty—December 31, 1903.

FOSTER, **M. H.**, passed assistant surgeon, granted leave of absence for four days from January 5, 1904—December 18, 1903.

RICHARDSON, **T. F.**, assistant surgeon, granted leave of absence for one month from January 1, 1904—December 29, 1903.

FOX, **CARROLL**, assistant surgeon, granted leave of absence for five days from October 31, 1903, under paragraph 191 of the regulations.

McCLINTIC, **T. B.**, assistant surgeon, granted leave of absence for seven days from December 26, 1903, under paragraph 191 of the regulations.

FRANCIS, **EDWARD**, assistant surgeon, to report to the Director of the Hygienic Laboratory for duty—December 17, 1903.

STIMSON, **A. M.**, assistant surgeon, granted extension of leave of absence for two days from December 15—December 22, 1903.

WARD, **W. K.**, assistant surgeon, granted leave of absence for one day, December 17, 1903, under paragraph 191 of the regulations.

SMITH, **F. C.**, assistant surgeon, relieved from duty at the Immigration Depot, New York, and directed to proceed to Detroit, Michigan, and report to medical officer in command for duty and assignment to quarters—December 18, 1903.

STEEGER, **E. M.**, assistant surgeon, to proceed to Clarksburg, W. Va. for special temporary duty—December 24, 1903.

GIBSON, **L. P.**, acting assistant surgeon, granted extension of leave of absence, on account of sickness, from November 20 to December 10—December 30, 1903.

HUME, **LEA**, acting assistant surgeon, granted leave of absence for twelve days from December 19—December 30, 1903.

TUTTLE, **JAY**, acting assistant surgeon, granted leave of absence for ten days from December 21—December 28, 1903.

BROCK, **G. H.**, pharmacist upon being relieved from duty at Detroit, Mich., directed to proceed to Delaware Breakwater quarantine station and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist **L. C. Spangler**—December 22, 1903.

GOODMAN, **F. S.**, pharmacist, relieved from temporary duty at Laredo, Texas, and directed to rejoin station at Norfolk, Va.—December 21, 1903.

ALLEN, **G. C.**, pharmacist, to proceed to Louisville, Ky., for temporary duty—December 19, 1903.

ILITIS, **G. W.**, pharmacist, relieved from duty at San Francisco, Cal., and directed to proceed to Detroit, Mich., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist **G. H. Brock**—December 22, 1903.

SPANGLER, **L. C.**, pharmacist, upon being relieved from duty at Delaware Breakwater Quarantine Station, to proceed to Boston, Mass., and report to medical officer in command for duty and assignment to quarters—December 23, 1903.

BIERMAN, **C. H.**, pharmacist, granted leave of absence for eight days from December 22—December 19, 1903.

Boards Convened.

Board convened to meet at the Marine Hospital, Stapleton, N. Y., January 4, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon **Preston H. Ballhache**, chairman; Passed Assistant Surgeon **A. C. Smith**, recorder.

Board convened to meet at Washington, D. C., January 18, 1904, for the purpose of examining certain officers to determine their fitness for promotion to the grade of surgeon. Detail for the Board: Assistant Surgeon-General **A. H. Glennan**, chairman; Assistant Surgeon-General **L. L. Williams**; Assistant Surgeon-General **G. T. Vaughan**, recorder.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 3.

JANUARY 16, 1904.

\$5.00 YEARLY.

The deficits of twenty New York hospitals, according to a report published in *Charities*, are as follows:

Hospital.	Annual Report for the Fiscal Year Ending	Deficit.
St. Luke's.....	Sept. 30, 1902	\$27,566.13
Roosevelt.....	Dec. 31, 1902	6,208.23
Presbyterian.....	Sept. 30, 1902	80,229.88
J. Hood Wright.....	Dec. 31, 1902	521.81
Woman's Hospital.....	Sept. 30, 1902	10,700.59
Flower.....	Sept. 30, 1902	8,224.34
Ruptured and Crippled.....	Sept. 30, 1902	55,675.27
Post-Graduate.....	Sept. 30, 1902	44,103.81
General Memorial (N. Y. Cancer Hosp.)...	Dec. 31, 1902	7,845.04
Montefiore Home and Hospital.....	Sept. 30, 1902	2,197.26
N. Y. Eye and Ear Infirmary.....	Sept. 30, 1902	6,106.06
Lying-in.....	Sept. 30, 1903	88,477.63
Mt. Sinai.....	Nov. 30, 1902	58,160.34
Lincoln.....	Sept. 30, 1902	586.35
N. Y. Infirmary for Women and Children	Sept. 30, 1903	6,678.36
Hahnemann.....	May 1, 1902	4,760.38
Nursery and Child's.....	Dec. 31, 1902	8,143.86
Orthopedic.....	Sept. 30, 1902	5,391.68
German.....	Dec. 31, 1902	9,841.15
Ophthalmic.....	Sept. 30, 1902	947.61
Total.....		\$432,868.78

The question is asked, how should this deficit be met, and from all the answers by correspondents there is but one worth any consideration. All the others are wide of the mark. As to how the deficit is actually met, in order that the hospitals may keep on, there is, however, one very exact answer: The endowment funds are applied to expense account. To a business man, of course, this method is financial folly.

Remedies for hospital deficits, proposed by Mr. Tucker's correspondents are briefly as follows:

1. By the public treasury, either *en bloc*, or on the *per capita* or *per diem* basis.
2. Small payments by the patients.
3. The city should pay for the destitute; other patients to reimburse the hospital.
4. Increase the tuition fees of the students of the affiliated medical school.
5. The use of unrestricted legacies to meet current expenses.
6. Appeal to the public for greater contributions.

With bluntness, Rev. Henry C. Potter answers:

Unfortunately, I dissent entirely from the premises on which the article is built, as I do not believe in the high value which the writer of the article places upon hospital treatment as compared with domestic treatment. His whole paper seems

to me a bid for the growth of institutionalism in a direction in which that growth is already becoming a menace.

Plans 1 and 3 are frankly socialistic, and in our political conditions, are held to be extremely dangerous. Plan 4 is as impractical as it is unjust. Plan 5 is in a business sense ruinous, and plan 6 has been already overworked, with the result that only one-sixth the money required has been secured. Bishop Potter's opinion elicits sympathy, but in fact it would be a reversion to medical barbarism, ill-treatment, increased length of illness of the sick, and increased amount of disease generally in the community. There remains the perfectly sound business plan, and the workable method of making all but the absolutely destitute pay something for their cards of admission, their medicines, etc. Even the destitute, so-called, could usually pay five cents or one cent. There is altogether too much sentimentalism about "destitution" and "charity" and "suffering humanity." Weed out the cheats who are able to pay the private physician; require a small fee from all who should and can pay a small fee; find if the destitute cannot pay even one cent; there will be left very few utter incapables. Exception, of course, to these rules may sometimes have to be made in case of those with highly contagious diseases. This plan encourages independence and self-respect on the part of hospital, physician, and patient, and it would at once free the hospital of its deficit, which is at present a disgrace to the physician, the hospital, the patient, and the public. Selfishness, sentimentalism and deficit are boon companions; the first is the patient, the second selfish charity, and the third the diseased hospital.

The duty of organization is in reality a self-interest and a necessity, and it must be carried out from one, the other, or from all motives combined. Dissension and individualism, whenever it has occurred has brought individual physicians to selfish and balked careers, and has reduced the mass to a condition of powerlessness as regards legislation and public sanitation, and has increased quackery and medical delusions a hundred-fold. Dr. McCormack finds that of 120,000 registered physicians in this country only one in four were members of any medical organization whatever. Alabama was almost a sole exception, and there the profession in the courts, halls of legislation, and executive

offices was honored, its advice heeded, and quackery was unknown. In Kentucky there was not an itinerant or advertising doctor in the State. Four years ago the American Medical Association Committee began its work, adopted as the first condition of reorganization the local self-government by the county society, and the House of Delegates of the State made up from county and district delegates, and electing its delegates to the House of Delegates of the national body exactly like the political method of our State and general government. The objections to coincident membership in county, State, and national societies which have been raised seem without force, or at least arouse only the question, "What other plan is more 'American?' or even more feasible?" This one, so far at least, is working out in practice, and any faults in it are most easily and readily changeable by the House of Delegates, in whose hands all power lies. Dr. McCormack in his powerful plea for peace and union in New York says:

The complex and difficult problems before the profession of this country, incident to our unprecedented advance in population and civilization, and which must be solved by it, if they are to be solved, will tax its highest intelligence and energies at its best. Provision can then be made for continuous scientific research, and for systematic collective investigation into the causes and prevention of disease, upon the large, generous lines demanded by the vast interests involved. The vexed problem of medical education can then be taken up with confidence and justly and wisely solved. Reciprocity in licensure and membership between States can then be discussed from the standpoint of the common good and settled upon some equitable basis. Constructive statesmanship can be substituted for the narrow time-serving political methods of the present in municipal, State, and national public health affairs, and our great profession, great even now in spite of its divisions, united, elevated, and ennobled, would come to occupy its rightful place as one of the greatest of modern forces for the guidance and protection of our people. It would be an honor, even to New York, to lead in a reform promising such results, and to set an example in complete organization, which less favored and weaker States would imitate with both pride and profit.

Union in New York, despite obstacles and difficulties, progresses, and Dr. McCormack reports that as a result of the recent conference of the committees of the two State societies even the details of the union have been agreed upon by nine out of 10 members, and now only an enabling act of the General Assembly is needed to effect the actual amalgamation. Of course, the plan of union is that already in successful operation in 32 States, and in over 1,500 counties, and which will doubtless be accepted by the rest of the States at the next annual meetings. The terms "un-American," "trades-unionism," "tyrannic," etc., have been applied to the method, and some opposition has appeared here and there. But it is generally believed that the criticism is based upon misconception, and that the constitution or reorganization of the American Medical Association is in fact according to American ideals and truly representative procedures. The following propositions concerning New York by Dr. McCormack appear either self-evident or demonstrated beyond controversy:

1. That existing professional conditions and estrangements are useless and senseless, that they are hurtful almost beyond calculation to both the profession and the public welfare, and that they are remediable.

2. That the plan of organization is based upon our system of civil government, that it was prepared with much care and unselfishness, and that it contains nothing untried, experimental, or impracticable.

3. That the county society is not only the unit of the organization, but the source of all authority and power in both the State and national bodies, through a representative delegate system, and it is also the only portal of entry to the entire society system.

4. That coincident membership has been an old and perfectly satisfactory method in many States, is essential to complete organization, and that it is just and right. It would be unfair to permit a physician to become a member of his county society and enjoy all the benefits arising from the labors of the State society, as to permit one to become a citizen of Ithaca or Troy without becoming a citizen of the State of New York and bearing the burdens and responsibilities of the same.

5. That amendment of any part of the plan is purposely made easy and is controlled by delegates from, and responsible alone to the county societies.

6. That the time has come for unification, and that, while union under a defective plan, which the joint body could modify and improve for the common good, would be far preferable to a continuation of existing conditions, the one now proposed has been found excellent and practical after full trial in other States, and, having been prepared away from New York contentions and controversies, it offers a basis for compromise honorable alike to both factions and to neutrals.

A Meeting in Baltimore to Discuss the Tuberculosis Congress Situation.—On January 28, 1904, at 8.15 p. m., there will be held in Baltimore, at McCoy Hall of the Johns Hopkins University, under the auspices of the Maryland Tuberculosis Commission, an informal meeting of American physicians and hygienists interested in the tuberculosis problem of this country. The object of the meeting will be to form a national committee to represent the American medical profession at the International Tuberculosis Congress to be held in Paris in 1905. There will also be a free discussion of the announced Congress on Tuberculosis in St. Louis under the leadership of Mr. Clark Bell, and the other tuberculosis congress to be held in Washington in 1905 under the leadership of Dr. Daniel Lewis, or as it is now called "The American Antituberculosis League." It is hoped that the deliberations at this meeting will result in an understanding between all concerned, and that all individualism and partisanship will be supplanted by true love to humanity, by genuine scientific and practical methods, and by the highest professional motives. If it is the unanimous opinion of the medical profession that there should be an American Congress on Tuberculosis previous to the one which is to meet in Paris next year, it should be thoroughly representative and an honor to the American medical profession. Professor Wm. H. Welch of Johns Hopkins will preside. All communications relating to this meeting should be addressed to the Secretary pro tem., Dr. H. Barton Jacobs, 11 Mount Vernon Place, Baltimore, Md. Those of our readers who are not yet familiar with the present tuberculosis congress situation in America, should refer to an open letter by Dr. S. A. Knopf of New York, entitled, "American and International Tuberculosis Congresses and Tuberculosis Exhibits for the years 1904 and 1905," which appeared in *American Medicine* December 5, 1903, and to our editorials on the subject then and since.

In the American crusade against tuberculosis the first noteworthy event of the year will be the Maryland Tuberculosis Exposition, to be held in Baltimore through the week of January 25. If the number and distinction of the men engaged can guarantee success, this exposition will amply justify the interest which it has excited. Even if their ambitious plans should not be fully realized, it is a novel and very striking idea of the Maryland Tuberculosis Commission to present this subject by means of an exposition. Their original purpose was to show in a graphic way as much as possible of the results of their own investigations, and to make beside a modest exhibition of the general movement against tuberculosis, hoping in this way to make a strong impression upon the people of Maryland. They have undoubtedly hit upon a means of most effective appeal to the popular mind, and it is not surprising that the plans of the Maryland Commission have arrested the attention of all who are interested in tuberculosis. The growth of the exposition was for a time embarrassing to its originators, who expected to give only a family party. But with the aid of the State Board of Health, the Maryland Public Health Association, and a large committee of influential citizens, the project will certainly reward the anticipations of visitors, and probably of its sponsors. The test of the value of the exposition will be the number of plain people who attend it. The list of speakers, among them Adami, Flick, Hoffman, Knopf, Ravenel, and Salmon, insures a genuine fest to the medical profession. But the people who will visit the exposition outside of lecture hours have most need of the lesson which the exposition is intended to convey, and if these people will be attracted in large numbers, the results of the exposition will be vastly better than the commission could have achieved by means of printers' ink. The keenest interest waits upon this experiment.

The Tramp as a Distributer of Disease.—The tramp has become a criminal, either actual or future, and though it may not always be possible to differentiate him from the honest, poor man seeking work, it should be done as a rule, and he should be photographed and classed in the rogues' gallery. Kindness to him, gifts of food or clothing, are really methods of making one *particeps criminis*. His role as a scatterer of the germs of disease has never been sufficiently well recognized. The reception he gets in households, towns, and cities on his routes is precisely that which brings to the citizens the surest chance that he will leave a trail of disease after him. He has syphilis or gonorrhea, or more probably both, he is filthy beyond description, and his associations are such that he is the prey of any infectious disease that is epidemic. The hospitals must periodically care for the criminal and clean him and cure him before sending him out again on his rounds of laziness and crime. His existence and that of his whole class is dependent upon the transportation he gets by theft or crime on railway trains. "Where there are no railroads there are no tramps." Do what they will, the railroads cannot prevent the many thousands of tramps from riding on their trains. His presence along the lines of

railroads is a constant heavy expense to the companies, and a menace to the health and property of the travelers and citizens. The railway companies are now organizing police departments to abate the danger and the nuisance, and the profession will be glad to cooperate, and much lies in its power, with city and town governments, and with the transportation companies to lessen the evil. Save the man if he is savable, but kill the tramp.

Reading in bed has recently been the subject of an extensive newspaper discussion in the *Daily Mail* of London. The results of the controversy are, of course, nil, each contributor doubtless being resolved, from the arguments of the like-minded, to do exactly what he has heretofore done, *i. e.*, to read in bed or not to read in bed, according to the convictions irrationally and indiscriminatingly formed before the newspaper undertook the office of public instruction. Like every other doubtful custom, this one may be good or bad, according to the method in which it is carried out. If the position is literally prone, the habit is unqualifiedly bad, because in such a position the eyes are fixed upon the book, in a straining and harmful way, and the book cannot be sufficiently and properly illuminated by the lamp or light used. But if one sits, propped up by pillows, in much the same position of the head and trunk as when in a chair, there can be no evil consequences, providing a good rich light is rightly placed behind and at one side of the head. The primary condition of scientific spectacles in case of the commonly existing refraction error should be observed, and is even more necessary in night reading than in that by daylight. The greatest argument for reading in bed is that the attention is not distracted by the discomfort of the body, the noises, and interruptions usual at other times. Let one take an erect position of the body and head, be assured he has a good oculist, and that his light is strong, white, steady, and properly placed; he may then read with impunity until drowsiness cautions him to stop.

Proverbial Wisdom as to Suppers.—The "supper" in our time and in city life has been displaced by the "dinner," but that does not change the old rules as to the advisability of going to bed or of not doing so "on an empty stomach." An old Italian proverb has it that, *Chi va a letto senza cena tutta notte si dimena*—"who goes to bed supperless, all night tumbles and tosses." Other proverbs advise the reverse of this. A Portuguese saying is, "If you would be ill, sup and then go to sleep." It is plain that the "potted wisdom" of proverbs will give no decisive rule as to digestion during sleep. The custom of an after-dinner nap is common in almost all Italian and Oriental countries, but it is contradicted by an old Latin proverb, *Post epulas stabis vel passus mille meabis*, which the Germans have capitally translated, *Nach dem Essen stehen oder tausend Schritte gehen*. An English saw runs: "After dinner sit awhile, after supper walk a mile." As a rule, one may perhaps say that the northern, and especially the Anglosaxon races, incline to think that digestion is not the best and easiest during sleep. But even here doubtless much depends

upon the kind of food eaten before sleeping. As to drinking, the people's experience is, that "he who goes to bed thirsty rises healthy." As age comes on digestion grows more difficult, so that the Spanish say, "Who steals an old man's supper does him no wrong." "An egg, and to bed," accentuates the advice. Habit is undoubtedly a chief element in the success or failure of the custom, so that there is much implied in the old saying, "Drink wine, and have the gout; drink no wine and have the gout, too." With our heartier and heavier food, most will probably agree that one should not sleep for two or three hours after eating.

A plea for the purification of hospital statistics is made by Dr. Wherry in the Bulletin of Iowa Institutions, which should be read by every hospital manager and trustee. It relates more to hospitals for the insane, but the general principles are as applicable and as needing application to others. We published last year figures of some hospitals which proved that if they had as many patients as figured in their reports every cot would have been occupied every night of the year by two or three sleepers. The old saying that figures will not lie, says Dr. Wherry, came from the times before the day of statistics. Physicians' reports he avers are generally most absurdly inaccurate, and all conclusions drawn from them and from hospital (for the insane) reports are worse than useless, they are perniciously misleading. As illustrations of this point he adduces instances of the mechanical filling in of the blanks of the answers of friends:

Q.—What is the cause of insanity?

A.—Melancholia.

Here the disease was mistaken for the cause. Again:

Q.—What is the cause of insanity?

A.—A love affair with a lady.

Of course, an ordinary love affair would scarcely be a sufficient cause for insanity, but when "with a lady," it becomes serious. Here is one which illustrates the danger of procrastination:

Q.—What is the cause of insanity?

A.—Come on slowly.

One of the most important causes, perhaps, of insanity is heredity, and it is receiving more and more consideration as an etiologic factor, but, whatever its significance in this respect, it has, more than likely, received much of its impetus, and gained much credit from statistics which are misleading. For instance:

Q.—Any relatives or ancestors insane?

A.—None.

Q.—What is the cause of insanity?

A.—Heredity.

Of course, all things are possible, but it is hoped that heredity, as a cause, rests upon a firmer foundation than this.

We have recently heard much concerning the alarming increase of the number of the insane. Dr. Wherry says that many "new" patients are in these lists who are in reality old ones and who have been previously admitted in other hospitals as new patients. As to the causes of insanity here is a finding:

In a report before me I find that 62 conditions, mental and physical, and ranging all the way from anxiety to vaccination, are given as the causes of insanity in 409 cases admitted to the hospital during the biennial period, while 234 were admitted with "no satisfactory cause assigned." Evidently the causes assigned for the 409 cases, such as blindness, excessive study, exposure, lactation, masturbation, novel reading, overwork,

and vaccination, must have been eminently satisfactory; and, if this is so, it would be extremely interesting to know what causes could possibly have been assigned to the 234 cases that would not give satisfaction. In the light of latter-day science, the 234 admitted with no satisfactory cause came much nearer the truth than a majority of the 409 who were so bountifully supplied with the causes which gave such unqualified satisfaction, for, while such a varied and diversified assortment of causes may give universal satisfaction, as tending to prove all theories and opposing none, this great etiologic multiplicity does not necessarily imply truthfulness and accuracy. To be sure these causes are only "assumed," but to the average mind, even though it dwell but in the suburbs of science, 62 causes for 409 cases seems to be "assuming" altogether too much.

This all comes from the fact that the cause is given as a rule by some friend or relative of the patient, who is present during the examination. These friends have watched all the details of the investigation with unabated interest and more or less excitement, and the solemnity of the occasion weighs heavily upon them. They feel keenly the responsibility of their position and are determined, should a cause be called for, that it shall be produced, no matter from whence or how, and that no member of their family shall ever be deprived of his due meed of insanity for lack of so simple a thing as a cause; and upon reading over the usual list of causes one can not but wonder at the boundless possibilities of the human mind under circumstances such as these.

"Lastly," says Dr. Wherry of these reports, "there are the statements it does not contain; the questions not answered at all. If 'knowing so much that isn't so' is bad, the next worst thing is not knowing at all, and throughout all our statistical tables a large and increasing army of the 'Unknown' marches grimly and steadily on. In a report before me I find that out of 313 patients admitted the ages of 63 were unknown; nativity of 44 unknown; occupation of 34 unknown; civil condition of 26 unknown; cause of insanity in 124 not even assumed; number of attacks in 50 cases unknown; duration of insanity before admission in 116 cases unknown."

EDITORIAL ECHOES

The W. C. T. U. and the Family Medicine Chest.—The South Side Woman's Christian Temperance Union of Rochester met a few days ago to discuss "The family medicine chest and what it should contain." When the attention of the members was called to the terrible fact that both belladonna and aconite contain alcohol there was no hesitation in deciding that they should be banished promptly. Every woman at this epoch-making meeting was armed with a list of the remedies an ideal family medicine chest should contain. When these had been well shaken together and diluted with a flood of discussion, it was found that the articles indispensable to the chest were: Syrup of ipecac, peppermint, wintergreen, nux vomica, vaselin, turpentine, ammonia, baking soda, glycerin, witch hazel, castor oil, nitre, bandages, flannels, borax, camphor, and quinin. Not a word was spoken for some of the good old remedies that have been cherished for generations: Cod-liver oil, sassafras tea, mustard plasters, and sulfur and molasses—all these were as if they did not exist. We may be persuaded to spare aconite and belladonna—they have a sort of homeopathic suggestion, anyway, not to speak of the devil that lurks in the alcohol they contain—but it would be only common generosity for the Rochester Woman's Christian Temperance Union to let us keep the good old remedies.—[*New York Evening Post.*]

BOOK REVIEWS

A Textbook of Clinical Anatomy.—By DANIEL N. EISENDRATH, A.B., M.D. Illustrated. Philadelphia: W. B. Saunders & Co. 1903.

This book is intended to supplement the knowledge of anatomy gained during the first 2 years of a medical course by applying that knowledge to the solution of bedside, clinic, and operating-room problems. The medical, as well as the surgical, aspects of these problems have been kept in view by the writer, with the result of producing a very well-balanced and useful book. The usual custom of considering in order the various regions of the body, beginning with the head, has been followed. The details of anatomy are not given, hence this work is not to be substituted for standard treatises on that subject. Two of the many valuable features of the book seem to the reviewer especially noteworthy. First, the constant directions for palpating structures that can be outlined in this manner. This endeavor to make the student or practising physician learn for himself the landmarks of anatomy is the highest ideal of teaching, and to him who follows carefully these directions the book will prove exceedingly useful. Second, the manner of illustrating the points mentioned in the text. The majority of the illustrations are original, a distinct relief in these days of copying from book to book. In the preparation of those showing surface outline the structures were traced upon artist's models and the subject then photographed, the results being most satisfactory. Röntgen ray pictures, especially of fractures, are also introduced. The publishers have aided in the clearness of the illustrations by supplying an excellent quality of paper. The book contains 502 pages of text and 155 illustrations. It can be heartily recommended.

The New International Encyclopedia. Volume XII.—Dodd, Mead & Co.

This number beginning with Maximilian I and ending with the New Jerusalem Church includes the following medical articles:

Measles	Mineral waters
Medical Association, American	Mint
Medical code	Monomania
Medical Department, Army	Monstrosity
Medical Department, Navy	Morphin
Medical education	Mouth, Diseases of
Medical school	Movement cure
Medical statistics	Mumps
Medicine	Muscae volitantes
Medico-Psychological Association	Musk
Medullary sarcoma	Myelitis
Melancholia	Myiasis
Memory (amnesia)	Myopia
Meningitis	Myrrh
Menstruation	Myxedema
Mental pathology	Nails, Diseases of
Menthol	Narcotics
Mercuric chlorid	Nausea
Mercury	Necrosis
Mesentery, Diseases of	Nematoda
Mesmerism	Nephrectomy
Metastasis	Nephrotomy
Methylene-blue	Nervous disease
Migraine	Neuralgia
Malaria	Neurasthenia
Milk	Neuritis
Milk cure	Neurology
Milk fever	Neurosis

Among subjects omitted or without cross reference are:

Measles, German	Milium
Mediastinum, Diseases of	Molluscum contagiosum
Melena of the new-born	Morphea
Ménière's disease	Muscles, Injuries to
Meningocele	Mushroom poisoning
Menopause	Mycosis fungoides
Methyl acetanilid	Mydriatics
Methyl chlorid	Myoma
Methyl salicylate	Myxoma
Methyl violet	Naphthol
Microcephalus	Neck, Injuries of

Only about half the usual quota of medical men receive biographic notice, although the number might have been swelled by such wellknown names as those of Ménière, Mikulicz, Minderer, Monsel, T. G. Morton, Murphy, Naegle, and

many others. There is no mention of the medical uses of mustard and naphthalin, and no reference to the involvement of the ovaries in mumps, or to eyestrain as a prominent etiologic factor in nausea. The long and otherwise excellent article on milk contains the merest allusion to its modification for infant-feeding, and nothing as to its pasteurization, or to its peptonization for the sick. The article on migraine is much more lucid than those intermittently contributed to medical periodic literature. Those on the historic aspects of medicine show excellent judgment in the selection of developmental events from a huge mass of material, and the other subjects treated receive the intelligent handling which is characteristic of this work.

The Medical Annals of Maryland—1799 to 1899.—By EUGENE FAUNTLEROY CORDELL, M.D. Baltimore, 1903.

This volume was prepared for the Centennial of the Medical and Chirurgical Faculty of Maryland in 1899, the committee in charge consisting of Drs. Osler, Ashby, Friedenwald, Hurd, and Preston. In the 889 pages of the work are embraced 3 divisions: (1) An historic section; (2) a biographic section; (3) a chronologic section. In the first is given a running account of the society during its first 100 years. The second contains the names of all the physicians who have been members of the society, with a brief medical biography of each. The third part is based on the historic researches of the late Dr. John R. Quinan, but has been extensively elaborated. The entire book gives evidence of the most painstaking efforts on the part of the compiler. Dr. Cordell was especially fitted to deal with this historic subject, as his recent appointment to the chair of the History of Medicine in the University of Maryland abundantly demonstrates. His wish that he might "produce a volume which will, for all time to come, be regarded as authoritative in all matters relating to the medical history of the State," will, we are sure, be fully gratified. The Medical and Chirurgical Faculty of Maryland is to be heartily congratulated upon the work of its first century.

The Medical Epitome Series.—Edited by V. C. PEDERSEN, A.M., M.D. **Physics and Inorganic Chemistry.**—By ALEXIUS MCGLANNAN, M.D. **Normal Histology.**—By JOHN R. WATHEN, A.B., M.D. Philadelphia and New York: Lea Brothers & Co., 1903.

These 2 volumes of this series maintain the high standard set by the editor in the beginning. They fulfil their purpose very well, that is for furnishing to the student or graduated physician a concise review of the subject in question. Though there are now almost numberless books of this type there is always room for first-class additions to the number. The editor of this series has been fortunate in securing men who use the limited space at their command to the very best advantage. The books average slightly more than 200 pages and are well illustrated.

Static Electricity and Electric Vibrations.—By FRANKLIN B. GOTTSCHALK. Published by T. Eisele, 906 Evanston avenue, Chicago.

This is a volume of 175 pages, devoted to a presentation of the most important mode of treating patients by means of electricity. The author, while a believer in the use of drugs and other methods of treatment, is yet an advocate of the use of static electricity in many properly selected conditions, and the little book is a result of his labors along this line. There are numerous illustrations which explain the method of administering electricity and the mechanics of the apparatus involved.

A Compend of Human Anatomy. Quiz-Compend No. 1.—By SAMUEL O. L. POTTER, M.A., M.D. Seventh edition revised and enlarged. Philadelphia: P. Blakiston's Son & Co.

This latest edition of Potter's wellknown work has been entirely rewritten to adapt it to the latest textbooks on the subject. The illustrations have been increased from 117 to 138. The tables and plates have been placed in their natural positions in the text instead of in an appendix. The size of the book has been increased by 82 pages. In this form the compend still maintains its place as one of the most valuable in the series, being a distinct improvement on the earlier editions.

AMERICAN NEWS AND NOTES.

GENERAL.

Medical Association of Porto Rico.—On December 27 and 28, 1903, there was held in San Juan, Porto Rico, the first annual meeting of the "Asociacion Medica de Puerto Rico" (Medical Association of Porto Rico). Several very interesting papers were read and discussed, marking an epoch in medicine in this Island, as it was the first time that scientific professional matters have been presented before a body of medical men here. This Association was organized a year ago, and includes now about 75 of the 200 (more or less) physicians of the Island. The meeting was enthusiastic, and the Association enters upon its second year of life in a prosperous condition, promising fair to become a power in the land. Its officers are: President, Dr. Manuel Quevedo Baez; vice-president, Dr. Ramon Ruiz Arnau; secretary, Dr. Rafael Velez Lopez; treasurer, Dr. Jose Carbognell. Dr. Francisco Goenaga is the other member of the board of directors.

Pure Food Legislation.—Pure food legislation was taken up on January 5 in Congress. Proposed amendments to the present laws were explained by Dr. H. W. Wiley, chief of the Bureau of Chemistry of the Department of Agriculture. He desired to add the word "foods" to the title of his bureau, making it "The Bureau of Chemistry and Foods." Another amendment suggested by the National Pure Food Association strikes out the words "with intent," in the provision against misbranding of food products, so as to relieve the government from the necessity of proving the intent to deceive in such action. Dr. Wiley explained the working of the law regulating the importation of foreign goods, the results of which, he said, were excellent, many cargoes of foreign foods having been refused admission to the country since last July. As many as 50 cargoes of German wines containing salicylic acid had been sent back. During the 6 months the law had been in operation, without suit or process of law, nearly all shipment of adulterated foreign foods had been stopped, although previous to the operation of the law 10% of all imported foods and drinks were adulterated.

Miscellaneous.—The former able editor of the *Cincinnati Lancet-Clinic*, Dr. J. C. Culbertson, having resigned, Dr. Mark A. Brown was chosen to fill his place. A portion of an editorial in the number of January 2 of that journal is as follows: In the last number of the old year was published a list of those who in the future will assume the editorial management and direct the policy of this journal. Since the complete staff has been made public, the editor has been overwhelmed with congratulations; nor does he take it much amiss that the felicitations have all been in the line of his great good fortune in securing so strong a corps of editors to assist him in the management of the several departments of medicine. He, too, is a little dazed at his success, for, without exception, all of his associates not only number among the leaders of their art, but stand for the dignity of medicine and its progress, and possess an ill-concealed animosity for any and every kind of quackery and clap-trap performance that would tend in the slightest degree to lower its tone. The word "policy" as applied to the *Lancet-Clinic* is rather a misnomer, for as in the past so in the future, there will be no policy other than truth and honesty, and a fixed purpose to give to its readers all that is best in our profession.

EASTERN STATES.

Lowered Deathrate in Cambridge.—According to the report of the Cambridge Board of Health, which has just been issued, the deathrate in that city is lower than it has been for many years. Last year the rate per thousand inhabitants was only 15.13. In 1902 it was 15.15; 1901, 16.83 and in 1900, 16.87. The number of all kinds of contagious diseases was less than it has been in previous years.

Boston's Lowered Deathrate.—The annual report of the Boston Board of Health for the year 1903 shows that there were about 10,640 deaths in the city during that year. The exact figure cannot be given. This makes a deathrate of 17.70 as against 18.73 in 1902 and 19.70 the year before that. No disease prevailed extensively enough during the year to be classed as epidemic. The mortality among small children also was smaller than last year. There were 68 cases and 13 deaths from smallpox, but that was early in the year, and the disease has not claimed any victims in Boston for many months.

Fire in Massachusetts Insane Institution.—On January 4, fire broke out in the Taunton Insane Institution, which threatened the lives of several hundred patients confined in the institution. The flames were, however, controlled, and no loss of life is reported, though serious damage was done to the hospital. The normal capacity of the hospital is 650 inmates; but 982 patients now are registered there. Of these, over 500 were in the women's wards. It is believed the damage to the building will exceed \$50,000. One of the most serious results of the fire was the destruction of the pathologic laboratory, the autopsy room, and the library of Dr. Miller, the hospital pathologist.

NEW YORK.

Cold Car Bill Introduced.—A bill has been introduced in the New York Legislature making it a misdemeanor for any railroad to run between November 1 and April 1 any car not properly heated.

Numerous Accidents in New York City.—The publication recently of figures showing that last year there were 458 persons killed in the streets in New York, whereas there were only 138 deaths from traffic accidents in London during the same period, has resulted in a campaign for legislation to control the reckless driving that prevails in New York City. The facts gathered by the newspapers show that beside the hundreds killed outright, fully 3,000 persons are disabled every year, more than twice the number killed or wounded in all of the railroad accidents throughout the country, by the almost criminal carelessness of drivers. The average driver is apparently utterly indifferent as to whether or not he runs down pedestrians, and it is an outrage to see helpless women have to rush to get out of the way of these ruffians on the box. In London the drivers have a wholesome respect for the policeman, who regulates traffic in effective fashion.

PHILADELPHIA, PENNSYLVANIA, ETC.

Health Conditions in Allegheny.—Contagious diseases reported to the Allegheny Bureau of Health for the 14 days ended December 26: Smallpox 21 cases; diphtheria 46 cases; scarlet fever 15 cases; typhoid fever 23 cases.

Health Conditions in Pittsburgh.—Contagious diseases and deaths from same reported to the Pittsburgh Bureau of Health for the 14 days ended December 26: Smallpox 45 cases and 14 deaths; diphtheria 55 cases and 18 deaths; scarlet fever 37 cases and 3 deaths; typhoid fever 290 cases and 23 deaths.

The Pittsburgh Academy of Medicine held an open scientific meeting January 5, having for its guests Dr. W. J. Mayo of Rochester, Minnesota and Dr. Albert J. Ochsner of Chicago. Dr. Mayo read a paper entitled "Ulcer and Cancer of the Stomach, from a Surgical Standpoint." The discussion that followed was opened by Dr. Ochsner. In the evening they were the guests of honor at the annual banquet of the Academy held at the Union Club.

To Prevent Child Labor.—The crusade against child labor in New Jersey will, it is believed, be crystallized within a few days in the formation of a permanent body, to be known as the Committee for the Protection of Children. The New Jersey Consumers' League has already taken up this question. At its invitation, many representatives of public and private educational and philanthropic organizations met in Newark and discussed the feasibility of forming a permanent child-labor committee.

Coroner's Statistics in Philadelphia.—Coroner Dugan, in giving out statistics of the work accomplished in his department during 1903, said it had been the busiest year in the history of the office. The number of inquests ran 553 beyond those of 1902—a total of 3,357. Certificates were issued in 1,018 cases in which the Coroner deemed inquests unnecessary, thereby saving the county expense. There were 58 homicides, an increase of 28; 202 suicides; 94 drowning cases, of which 63 were accidental, 6 suicidal and 25 undetermined; and 932 casualties, including steam and street railway cases, injuries from vehicles, falls from windows and on the street, down elevator shafts, and by machinery, an increase of 118. One hundred and forty-two persons died from scalds and burns; 20 were accidentally suffocated at their homes, 4 at fires, and 109 by coal and illuminating gas, of which number 43 persons were suicides. There were 254 casualties on steam and electric railways, an increase of 42, distributed as follows: Pennsylvania Railroad, 116; Reading Railway, 71; Baltimore and Ohio Railroad, 8; West Jersey and Seashore Railroad, 3. The casualties on the electric railways were: Philadelphia Rapid Transit Company, 53; Southwestern Company, 2; Chester Traction Company, 1.

Mortality in Philadelphia for 1903.—The annual report of the Bureau of Health, made public recently, shows a death-rate of 18.82 per 1,000 of population, the lowest rate, with 4 exceptions, since 1879. In 1897 the rate was 18.72, in 1899, 18.78, in 1901, 18.26, and in 1902, 17.67. The total of deaths for the year was 25,947, as compared with 23,847 for the previous year, the greatest increase being from typhoid fever, from 585 in 1902 to 957 last year. An infected milk supply and failure to observe the oft-repeated warning to boil all drinking water not filtered is held accountable for the heavy increase in this disease. The greatest total of deaths was from pneumonia, 3,180, as compared with 2,976, with tuberculosis a close second with 3,053, an increase over the preceding year of 208 cases. Deaths from smallpox numbered 278, 47 more than occurred in 1902. But 3 cases of malarial fever ended fatally during the year. The cases of contagious diseases in 1903, as compared with those in 1902, were as follows:

	1902.	1903.
Smallpox	1,842	1,637
Diphtheria	2,444	3,043
Typhoid fever	5,006	8,650
Scarlet fever	3,161	3,200
Totals	11,953	16,530

WESTERN STATES.

Indians Going Insane.—The National Hospital for Insane Indians, at Canton, S. D., has finished its first year. At the beginning it had 34 patients, half of its capacity. In a few months it was filled. According to Superintendent Gifford the number of insane Indians is constantly increasing, the chief cause being dependency. Lack of active occupation, hunting and the like is the chief cause of this.

Why many Cases of Tuberculosis are not Cured.—The Cincinnati *Lancet-Clinic*, of January 2, commenting upon this subject editorially, says: "The statistics of those experienced in the treatment of tuberculosis have shown that in order to obtain favorable results the patient must be secured when the disease is in the first stage, or stage of infiltration. Judging by the experience gained in the Cincinnati Branch Hospital for Consumptives, we feel this is the greatest stumbling-block to success, and will exist until physicians and the general public recognize the necessity of earnest efforts when the disease is in its incipency. One cannot but feel at times that the reliance upon the sputum examination for diagnosis is one of the factors which will lead to a paucity of favorable results. That physicians do rely upon the microscope to a large degree is shown by some of the death returns in our Health Department. Several physicians signed the certificate "supposed to be consumption, but the sputum examination was negative." A physician who will wait until the lungs break down sufficiently to result in the throwing off of tubercle bacilli, or who will rest satisfied with the results of 1 or even 2 or 3 sputum examinations when reported negative, is guilty of withholding from his patients valuable opportunities for recovery. Neither the microscope nor the Röntgen ray can substitute a competent physical examination, although they are invaluable in some instances as confirmatory factors.

CANADA.

Typhoid Epidemic in Montreal.—There are approximately 1,000 cases of typhoid fever in Montreal and the half dozen smaller municipalities which join it on 3 sides. This alarming total is being added to rapidly, despite the vigorous precautions adopted a week ago to forestall the spread of the disease. Police-men have gone from house to house distributing printed warnings that a serious typhoid epidemic exists, and urging householders to boil their drinking water. In the meantime, bacteriologic tests will be made of the water.

FOREIGN NEWS AND NOTES

GENERAL.

Operated upon Only 84 Times.—A man who has survived 84 surgical operations lives at Guisborough, an old world market town in Yorkshire, England, at the foot of the Cleveland Hills. For over 30 years he has suffered from the ravages of the hungry disease known as lupus. Having reached that stage of life, which, under normal conditions, would be a man's prime, he is still an intense sufferer. The man still hopes to be cured.

To Combat Tropical Diseases.—Three medical experts in the service of the French Government departed on the steamship *Mariposa* for Tahiti, where they will endeavor to check the ravages of disease among the natives. The experts include Dr. H. Louvan, Dr. F. Cassiau and Dr. Grosfellez. These men are authorities on leprosy, elephantiasis and other tropical diseases, and have been sent because of the increase in mortality among the natives. The doctors will be given certain judicial powers to aid them in enforcing such sanitary laws as they may adopt.

Treatment of Tuberculosis in Germany.—The German Central Committee for Tuberculosis publishes some interesting statistics concerning the results of the open-air treatment of tuberculosis. During the year 1902, 12,187 tuberculous men and 4,302 tuberculous women were treated in open-air hospitals at the expense of the Imperial Workmen's Insurance Office. Of this number 78% were so far healed that there is no prospect of the disease rendering them incapable of work. If those cases are deducted in which after a fortnight's treatment, it was evident that no cure could be effected, the successful cases numbered 81%. Figures published by the Imperial Statistical Office show that the deathrate from tuberculosis in German towns of 15,000 and more inhabitants is steadily decreasing. The number per 10,000 who died of tuberculosis in the 5 years ending in 1881 was 357.7; in 1886, 346.2; in 1891, 304.5; in 1896, 255.5, and in the 5 years ending 1901, 218.7.

OBITUARIES.

James Francis Ferguson, at his home in Central Valley, N. Y., December 30; a graduate of the Medical Department of the University of New York, in 1861, and from the Bellevue Medical College, in 1862.

He served with the Second New York Militia during the early part of the war and was at one time confined in Libby prison. He was with General Banks in Louisiana and was afterward provost surgeon in New Orleans. His professional appointments were as follows: Attending surgeon, Bellevue Hospital, Outdoor Department, 1870-71; visiting surgeon to the Blackwell's Island Hospital, 1872-92; visiting physician to the Hospital for Nervous Diseases, 1886-92, and consulting physician of the Charity (now City) Hospital, since 1892. He was a member of the alumni of Bellevue Hospital Medical Society of the County of New York, New York Academy of Medicine, the New York Neurological Society, Military Order Loyal Legion, Lotos Club, Army and Navy Club, Kane Lodge, No. 451, F. and A. M., Jerusalem Chapter, No. 8, R. A. M., Coeur de Lion Commandery, No. 23, K. T., and a thirty-third degree Scottish Rite Mason.

George H. Hackenburg, a noted scientific man, who is credited generally with being the originator of the telephone idea, died at his home in Austin, Tex., recently. He was 80 years old. In 1864 he wrote an article, which was published, making public his ideas of the principles of the telephone, which were afterward practically applied by others. The article attracted wide attention. He was at that time living in Ohio. He was born in Union county, Pa., and was a graduate of the Medical College of New York University. He practiced medicine in New York State for several years, and was a frequent contributor to magazines on scientific subjects. He moved to Texas in 1873.

Charles G. Frowert, suddenly, at his home in Philadelphia, January 9. He was a well-known physician of the city, having graduated from the University of Pennsylvania in 1874. He was a thirty-second degree Mason and a Knight Templar, and took an active interest in secret society affairs. He was a member of the Pennsylvania Medical Society, the Philadelphia County Medical Society, the American Medical Association, and other medical associations. He was medical director for many large life insurance companies, and trustee of the Presbyterian Church of the Covenant at Cynwyd.

George Winslow Foster, at his home in Bangor, Me., recently. He was at one time connected with the Insane Hospital at Taunton, Mass., and labored in the same capacity in the Government Hospital at Washington, D. C. In 1901 he was called to the position of superintendent of the Eastern Maine Insane Hospital, at Bangor. He was a graduate of Bowdoin College in 1871, and later of the Maine Medical School, a member of the American Medical Association, the Washington, D. C. Medical Association, and the Penobscot Medical Association.

Stewart H. Reed, at his home in Madison, N. J., January 6, from pneumonia. He was a graduate of Williams College, Mass., in 1878, and the College of Physicians and Surgeons of New York, in 1881; a member of the Board of Chosen Freeholders for Chatham township, member of the first Board of Councilmen, one time member of the Board of Education, one time physician for the Board of Health, and a member of various medical societies.

Benjamin H. Hartwell, at his home in Ayer, Mass., December 30. He had been a pension examiner for 28 years, and examining physician for many prominent organizations and companies. He was a graduate of Lawrence Academy and of Jefferson Medical College, Philadelphia; one time coroner in his home city and for 8 years was connected with the medical department of the Massachusetts militia.

Frank M. Shaw, on January 3, in the Seney Hospital, Brooklyn, from an overdose of opium taken to relieve the dreadful pain of facial neuralgia; a graduate of the College of Physicians and Surgeons of New York, and one time a member of the staff of the Presbyterian Hospital. He was a member of the King's County Medical Society and various local clubs.

Cornelius E. Billington, at his home in New York, January 8, aged 60; he was a graduate of the medical department of the New York University, in 1864 and was a well-known writer, and the author of a work on diphtheria and its treatment.

Owen Campbell Brown, at his home in Detroit, Mich., recently after an illness of 3 months; a graduate of Toronto University and examiner for the Knights Templar, Masons, and Life Insurance Company of Chicago.

Edward L. Griggs, at his home in Waterbury, Conn., December 30, of heart disease. He was one of the oldest and best known physicians in Waterbury, and a graduate of the Yale Medical School, in 1864.

Margaret P. Buckman, at her home in Trenton, January 7, from scarlet fever contracted while caring for her child. She was a graduate of the Woman's Medical College of Philadelphia.

Harrison Baker, at his home in Baton Rouge, La., January 5, at an advanced age. He was a native of Pennsylvania, but had resided in Baton Rouge for the past 6 years.

L. S. Major, at his home in Austin, near Chicago, January 3, aged 61. Dr. Major came to Chicago in 1848, and erected the Major Block on La Salle street, in that city.

H. A. Chors was found dead January 8, in the rear part of a drug store in Brooklyn. He was 37 years old, and a graduate of the Long Island College Hospital.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

APPENDICITIS.¹

BY

J. J. BROWNSON, M.D.,
of Dubuque, Ia.

Member American Medical Association; Surgeon to Mercy Hospital; Surgeon to St. Mary's Orphanage; President Board of Commissioners of Insanity, Dubuque County, Ia., etc.

Appendicitis, its diagnosis, prognosis, and treatment, holds the "boards" as one of the most interesting and profitable subjects for medical men to consider, and therefore it may be of interest to relate the principles upon which I have based my method of operative procedure in cases of appendicitis:

Many years ago Dr. Fowler called me in consultation to Bellevue, Iowa. The patient, Mr. S., had been sick about 3 weeks with supposed inflammation of the bowels. He had passed through all the usual symptoms of pain, fever, vomiting, etc. After the distention had subsided there remained a circumscribed swelling in the right iliac region. Several consultants had seen the patient, and all advised the then prevalent, expectant treatment. The patient was hectic and had all the usual symptoms of encysted abscess, which physical examination confirmed. I advised operation. Ether was administered and I cut down upon the swelling, opening into a large collection of pus. After evacuation the cavity was lightly packed with gauze and the ordinary dressings applied. After 3 days the wound was dressed, and upon removal of the gauze there was a profuse discharge. The patient eventually made a good recovery. This was my first operation for appendicitis.

Later, I was called to a similar case, with Dr. Loose, of Maquoketa. The patient, Mrs. S., aged 60, was a resident of Otter Creek, Ia. She had been sick about 3 weeks. Dr. Loose stated that he had made a diagnosis of typhlitis. Upon examination there was dullness, tenderness, edema, and some rigidity in the right iliac region. This condition, together with the hectic symptoms was indicative of pus. We therefore decided to operate. Doctor Loose administered ether. On opening the abdominal cavity, gas, and some dirty, sanious-looking pus exuded, the odor was very foul and decidedly fecal. The wound was packed with gauze and the usual dressing applied. After several days the wound was dressed, and upon removing the gauze the discharge was profuse. Drainage was maintained, and after a time the patient recovered.

Patients of this class kept coming, and we now realized that a case in which the onset of the disease was marked by vomiting, constipation, pain in the right side, fever, etc., was not inflammation of the bowels, but appendicitis, which was becoming the much talked of, much investigated, modern, and much operated upon disease. Nearly all surgeons advocated immediate operation and removal of the appendix as soon as the diagnosis was made. Several of my contemporaries adopted this plan, and almost invariably there was a fatal termination in cases operated upon by them. This led me to investigate the reason for such difference in results. I discovered that the appendix was always removed in these pus cases, while I never removed it under such circumstances. Again, I took the reasoning of the older authors, that intermediary operations were always accompanied by a larger mortality than either primary or secondary. It occurred to me, therefore, and the clinical results proved that if this was true in ordinary operations—amputations, etc., it must be doubly so in cases in which the abdominal cavity and peritoneum are involved. I therefore followed a method of procedure many years ago which has been continued by me with the most successful results. I shall describe this method later.

There have been more deaths from appendicitis since the operative method has been in vogue than during the expectant plan, which I believe is due to interference being practised at the wrong time.

There are, in my judgment, three periods when the operation can be safely performed:

1. At the inception of the disease before fever, or in the primary period, when the appendix should be removed.

2. After the fever and distention have subsided and suppuration has taken place, when the cavity ought to be drained and nature allowed to take care of the appendix.

3. In the interval after all signs of inflammation have disappeared, when the appendix should be removed. In the first period, if done early, the mortality ought to be very low. In the second period, the fatal cases are nearly always due to the zeal with which operators go after, and persist in getting the appendix. They break down the adhesions, thus producing septic peritonitis and death. It is not necessary to remove the appendix in this stage, since nature will remove the offending part of the appendix, and all that is necessary is incision and drainage. I use gauze packing and even hesitate to make any exploratory examination. I have demonstrated this to be a safe and successful method by treatment of numerous patients. The third period is a very safe time and should be recommended to patients, especially after a second acute attack. As advocates of the plan for immediate operation, the only reason is that we never know what the appendix is going to do, but on reflection it is only the so-called fulminating cases, or those in which the abscess bursts directly into the peritoneal cavity, that result badly, terminating fatally, almost before anything can be done. In these cases the damage is usually done before the patient is seen by a physician. So it is right here that we ought to consider whether every patient should be subjected to a critical operation to prevent a circumstance which happens but rarely. The whole question hinges on how to prevent the fulminating cases. In which of the three periods do these cases most generally occur? If in the intermediate period, which would be the greater danger, to operate during this period or run the risk of the case becoming fulminating? Would there be fewer deaths after 100 operations in this period than if left to run the risk of becoming fulminating? Any but the ordinary fulminating case can be, or should be, determined by the ordinary practitioner, and when the case progresses it will go on to resolution or to the formation of adhesions and abscess. When an abscess forms, sufficient evidence is given of its presence, so that it may be opened before it bursts into the abdominal cavity. If this opening and draining and allowing nature to take care of the appendix is properly done, there should be practically no mortality. I regard the anxiety about the abscess bursting as a sort of bugaboo, which has led to the desire for immediate operation and removal of the appendix. As before stated, this condition ought to be determined before the abscess becomes so large as to burst. I have never seen a case of abscess of the appendix with adhesions that did not give plenty of evidence long before the fatal perforation took place. If, now, we can eliminate the fulminating cases, and the abscess with adhesions, I need not mention that it is useless to operate upon patients after the septic contents have been poured out into the abdomen, causing septic peritonitis; it is a forlorn hope, and will only bring odium on the legitimate operation.

Summing up all the facts we find it is those cases in which rupture occurs directly into the peritoneal cavity over which we have no control. In all other cases there are peculiar symptoms and physical signs by which we may determine in time the patient's condition and institute such operative procedure as will conduct the case to a successful termination. I believe the "operate-and-remove-the-appendix-as-soon-as-the-diagnosis-is-made plan" should be modified, and the condition of the patient and the period of the disease made the basis for active interference, following out, as directed, the plans laid down.

In the first and third stages the technic is fully settled and whether we amputate or invaginate should be left to the judgment of the operator. In the second stage, the operator should cut freely down and open the cavity with care. As soon as pus appears no further interference should be attempted, except to pack lightly with gauze and put on a combination dressing. After three or four days, when nature has walled off and protected the sides of the wound, the gauze may be removed and ample drainage will be found. By this method we run no risk of infecting the wound. In other words we give exit to the pus; nature does the rest. I never remove the appendix in this stage and I have followed this plan in a great number of cases always with successful results. It may be urged that by this method the disease will recur. I have never seen but one recurrence. If it should recur there is no danger of the pus bursting into the abdominal cavity, for it will follow the old scar and

¹ Read at the meeting of the Austin Flint, Cedar Valley, Medical Society, at New Hampton, Ia., November 10, 1903.

open externally; the scar tissue always being the point of least resistance. On the other hand, if you insist on exploring the wound and removing the appendix it enhances the danger and is of no practical benefit.

I was recently called in consultation by Dr. B. A child had been sick 3 weeks with the usual symptoms of appendicitis. The distention had gone down, and there was a tumor, the outline of which could be made out in the right iliac region. The child had trouble with the urine, caused by pressure on the bladder. She was hectic and suffered some pain. A diagnosis of appendiceal abscess was made, and operation advised and accepted. Chloroform was administered, an incision was made, and gauze drainage instituted. The child recovered.

About the same time as the foregoing case one of my friends who belongs to the "operate-immediately-and-remove-the-appendix" class had a patient with a similar case. The patient was in the intermediary stage, high fever, and distention, and he as usual operated, removing the appendix, and as usual with such operations in this stage, the child was dead the next day. The appendix contained a large concretion, but had no rupture. This patient did not die from lack of operative skill, but because the procedure was adopted at the wrong time—in the intermediary period, when there was distention and fever, the peritoneum already struggling to protect itself could not stand the increased invasion of operative procedure, and the patient succumbed.

Perhaps many of my readers have attended patients with appendicitis having the usual symptoms, and in whom, after distention of the abdomen went down, a swelling or lump was left in the right side. The physical signs gave fluctuation, and yet the tumor went away, and the patient recovered. How can we account for this? This leads to the question, was it pus? If so, is pus ever absorbed? I do not think pus ever is absorbed. As to cases in which the lump disappears, I think a circumstance which occurred in the following case will solve the problem:

L. S., aged 9, became sick on Monday with vomiting and pain in the umbilical region. I saw him on Wednesday; there was fever, tenderness, and rigidity in the right side. I diagnosed appendicitis, and said he probably would require an operation. The next day the patient seemed to be better, with less distention and fever, tumor, dullness, and signs of pus in the right side. On Friday, Dr. Boothby saw him in consultation with me, and we thought it best to operate. As it was in the afternoon when we reached the house, and the hour was growing late, we compromised on aspiration. After applying ice and salt to anesthetize the parts, we introduced the needle and found, much to our surprise, not pus, but fluid. The outcome of the case was as follows: We had evidently infected the patient, for the next day he had a chill, and the day following, when I saw him, we aspirated again, and this time it showed pus. Incision and drainage was then done in the usual way, and the boy recovered.

Here, then, is probably the explanation of cases in which there is tumor and signs of fluctuation, and in which the patients recover without operation or its bursting into the bowel or bladder. The tumor contains fluid which becomes absorbed, and not pus. It is a fluid something similar to the fluid in a case of pleurisy. This was new to me, for it was the first time that I had reflected that the serous membrane covering and surrounding the appendix, when inflamed, produces, like other serous membranes, fluid, which when not infected is absorbed. I have not seen this fact mentioned in any of the textbooks. In this second stage, how are we to tell that this enlargement with signs of fluctuation is serum, and not pus? By the absence of hectic, the rigidity and the tenderness will be less, and there will not be such inflammatory edema. Also, I think the length of time and the absence of chill will help to form an opinion. In case of any doubt, aspiration with a sterile needle can be done, which, if performed with care, will do no harm.

CONCLUSIONS.

1. The operation for appendicitis ought to be done in the primary or before fever period. The appendix should be removed, to guard against fulminating cases and those in which rupture occurs into the abdominal cavity.

2. In the secondary period after suppuration, drainage should be instituted, and nature left to take care of the appendix.

3. In the interval, after all symptoms of inflammation have subsided, when the appendix should be removed.

The operation ought not to be done in the intermediary period when there is fever and distention of the abdomen, because the *danger* from operation at this period is greater than the *risk* of the case becoming fulminating, or the abscess bursting into the abdominal cavity.

I have operated on numerous patients with appendicitis, and when the operation was based upon the foregoing principles, have never lost a case.

THE UNIFICATION OF THE MEDICAL PROFESSION IN THE STATE OF NEW YORK.

To the Medical Profession of the State of New York.

Editor of American Medicine:—The sub-committee of the Joint Committee on Conference presents the following plan of consolidation of the Medical Society of the State of New York and The New York State Medical Association for the information of the medical profession of this State.

The plan is the result of much labor, legal investigation and careful thought and attention on the part of the committee; and the organization recommended for the consolidated corporation is one which is now in successful operation in 32 States of the United States. It is based upon the form of government of the United States and care has been taken not to interfere in any way with the autonomy of county organizations, or with their property or other vested rights.

We respectfully urge the members of the profession to promote by all proper means the passage by the Legislature of the proposed Act prepared by counsel for the committee, authorizing the consolidation of the Medical Society of the State of New York and The New York State Medical Association. The proposed act will be introduced in the Assembly or Senate in due course, and if passed, will authorize the consolidation upon terms to be agreed upon by the 2 corporations. The consolidated corporations will be known as the Medical Society of the State of New York.

Before the agreement for consolidation under the proposed act will become operative or effective for any purpose, it must be authorized or ratified by the vote of each corporation at an annual meeting, or else, at a special meeting of each corporation called to vote upon the agreement, and it must also be approved by the county medical societies in affiliation with the Medical Society of the State of New York.

The agreement to be recommended by the committee for adoption in accordance with the terms of the Act, will contain provisions for giving effect to the following stipulations:

1. All assets and liabilities of The New York State Medical Association shall be transferred to and vested in and assumed by the Medical Society of the State of New York at the time of consolidation.

2. Expert accountants shall be employed to ascertain the assets and liabilities of each corporation, and their reports shall be submitted with the agreement for consolidation.

3. All members of The New York State Medical Association in good standing at the time of the consolidation shall be admitted to membership in the Medical Society of the State of New York.

4. All members in good standing of the county medical societies now in affiliation with the Medical Society of the State of New York shall be admitted to membership in the Medical Society of the State of New York.

5. All members in good standing of The New York State Medical Association shall be admitted to membership in the county medical societies for the counties in which they respectively reside.

6. All members in good standing of the Medical Society of the State of New York shall be admitted to membership in the county medical societies for the counties in which they respectively reside.

7. The plan of organization, constitution and by-laws of The New York State Medical Association, with such modifications as have been agreed upon by the committee, shall be adopted

as the plan of organization, constitution and by-laws of the Medical Society of the State of New York.

8. The following proposition shall be submitted by referendum to the vote of the members of the consolidated corporation, namely:

The principles of medical ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public.

9. The Medical Society of the State of New York will petition the Legislature for the passage of such further enabling act as may be necessary, if any, to carry the consolidation agreement into effect.

AN ACT

TO AUTHORIZE THE CONSOLIDATION OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK AND THE NEW YORK STATE MEDICAL ASSOCIATION.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

SECTION 1.—The Medical Society of the State of New York, incorporated by or pursuant to chapter one hundred and thirty-eight of the laws of eighteen hundred and six, entitled "An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this state," and continued by chapter ninety-four of the revised laws of eighteen hundred and thirteen, passed April tenth, eighteen hundred and thirteen, entitled "An act to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this state," and The New York State Medical Association, incorporated under chapter four hundred and fifty-two of the laws of nineteen hundred, may enter into an agreement for the consolidation of such corporations, setting forth the terms and conditions of the consolidation and the mode of carrying the same into effect.

Each corporation, party to the agreement, may petition the Supreme Court for an order consolidating the corporations, setting forth in such petition the agreement for consolidation and a statement of all its property and liabilities and the amount and sources of its annual income. Before the presentation of the petition to the court, the agreement must be approved by a majority of the vote lawfully cast at an annual meeting of each corporation, separately, or at a meeting of each corporation separately and specially called pursuant to its by-laws for that purpose, and a certificate of such approval, verified by the president and secretary of the meeting shall be annexed to the petition.

On presentation of the petition, the certificate of approval and the consolidation agreement, and on such notice to interested parties as the court may prescribe, and after hearing such interested parties as desire to be heard, the court may make an order for the consolidation of the corporations on such terms and conditions as it may prescribe.

When the order is made and duly entered, the corporations, parties to the agreement, shall be one corporation under the name "Medical Society of the State of New York," which shall not be deemed to be a new corporation, but to be a continuation of the Medical Society of the State of New York, incorporated in eighteen hundred and six. A certified copy of said order shall be filed in the office of the Secretary of State. All the property belonging to the corporations so consolidated shall vest in the said Medical Society of the State of New York, which shall have all the powers, rights and privileges possessed by either corporation at or immediately prior to the consolidation, and which shall be subject to all of the liabilities of each corporation.

Sec. 2.—This Act shall take effect immediately.

Respectfully submitted,

A. JACOBI,
GEORGE RYERSON FOWLER,
E. ELIOT HARRIS.

THE TEMPERATURE CURVE.

BY

LOUIS FAUGERES BISHOP, A.M., M.D.,
of New York City.

We are constantly discussing the temperature charts of various conditions, so it might be well to consider what the temperature curve really is. There are some things that are perfectly well known which it is worth while to review or to observe from another point of view.

Much that cannot be explained in language can be expressed by mathematic symbols, such as the temperature curve. This is indeed a wonderful invention, in that it can express by 1 symbol 2 quantities of entirely different kinds. In the temperature curve the 2 elements expressed are time and the degree

of fever. These quantities are presented to the eye and mind by a properly constructed temperature chart better than is possible in any other way, but to give an accurate impression, the curve must be properly drawn.

In filling in the chart, very rarely is any error made in placing the point at the proper temperature, but on the other hand, the element of time is seldom expressed by putting the point in the proper place, so that if 6 different nurses should keep a chart of the same patient without comparing notes, it would not be surprising if there were 6 different curves. This, in dealing with a mathematic subject, is absurd. The intelligent physician discounts the error by a study of the chart.

The distance on a temperature chart from below upward represents the temperature; the distance from side to side represents time; the temperature distance is usually subdivided when the chart is printed, the time distance being left for the nurse to subdivide. Usually the nurse leaves from a quarter to an eighth of an inch for each observation of temperature, irrespective of the lapse of time. The result is that the temperature taken 15 minutes after a cold bath is given the same space as if 4 hours had elapsed since the previous observation.

What should be done is that the distance from right to left allowed on a chart for 24 hours should be mentally or actually divided into 24 spaces, and each observation recorded in exactly the proper position, then when the points are connected the curve will be a mathematic curve, representing in a wonderful way the relation of 2 quantities of a different character—time and temperature.

A WEDGE MOUTH GAG.¹

BY

FREDERIC GRIFFITH, M.D.,
of New York City.

Fellow of the New York Academy of Medicine.

Five years ago I had under my care a case of melancholia in a male. One of his fixed delusions consisted in a belief that his food was poisoned, consequently he refused to eat. Forced artificial feeding was therefore carried out continuously by means of a gag and stomach tube and it is with a description of the gag used which we found so efficacious in this case that this article has to deal. Credit for the invention is due to James Connolly, my day nurse.

Simple in design the model which I have made consists of a wedge-shaped block $7\frac{1}{2}$ inches long, $1\frac{1}{2}$ inches wide, $\frac{3}{4}$ inch thick

Figure

at the base with bevelled edges tapering to an edge at the apex.

Locust or beechwood is best used in the manufacture because they are tough and do not splinter or split.

To force open the jaws of a patient the wedge is grasped and inserted between the teeth manipulating in the same manner as an oyster-knife is used to pry open oysters.

This instrument has the advantages of cheapness, durability, ease and security in manipulation and of reducing to a minimum the danger of teeth cracking. It should be included in every anesthetizing outfit.

Improvement Accomplished by the Present Health Officials of Chicago.—The Bulletin of the Chicago Health Department, for the week ended January 2, says that the present Commissioner of Health was originally appointed in 1893, and recently reappointed for a fifth term. Comparing the corresponding period prior to 1893 with the period ended 1903, the chronologic summary of Chicago mortality shows a reduction in the general mortality from 24.35 to 15.97 per 1,000 of population, with a constructive saving of upwards of 79,500 lives at all ages and of 55,000 lives of infants and young children. It shows a decrease of more than a fifth (22.4%) in the tuberculosis death-rate; a decrease of 70% in the diphtheria mortality; and of more than three-fourths (75.9%) in the typhoid fever rate.

¹ Presented at the Academy, Surgical Section, December 4, 1903.

CANCER OF THE STOMACH. A REVIEW OF CASES FROM THE STANDPOINT OF DIAGNOSIS AND MEDICAL AND SURGICAL TREATMENT.¹

BY

JAMES RAE ARNEILL, A.B., M.D.,
of Denver, Colo.

Associate Professor of Medicine in the University of Colorado.

Cancer of the stomach, when considered in a broad, comprehensive manner, often furnishes interesting and difficult problems in differential diagnosis. Its symptomatology is so remarkably variable and its signs so inconstant that there are no pathognomonic evidences of the disease, taken as a whole. This we would expect from a consideration of its pathology. One patient comes to us in the advanced stages of the disease, when a mere novice could make a diagnosis; another comes with the disease in its very incipency, when a Riegel or an Ewald would confess himself baffled. In one case the newgrowth is located at the pylorus; in another the tumor involves the cardia; in a third the lesser curvature; while in yet another it is the fundus which is diseased. In one the growth is hard and of the scirrhus variety; while in another an ulcerating and encephaloid cancer is found; in a third there is perhaps a carcinoma developing on the base of an old gastric ulcer.

In one there are symptoms of a profound toxemia; in another chiefly evidences of starvation; in yet another, symptoms of stenosis and dilation of the stomach. Is it any wonder, then, that when considered in its entirety with its multiplicity of symptoms and signs, frequent mistakes of omission and commission are made?

In my experience, cases of cancer of the stomach have been most frequently mistaken for, (1) chronic atrophic gastritis; (2) pernicious anemia; (3) ulcer of the stomach; (4) gastric neuroses and enteroptosis; (5) tuberculosis, Bright's disease and heart disease; (6) abdominal newgrowths involving other organs and tissues.

In many of these cases mistakes would often have been avoided if careful laboratory examinations of the blood and gastric contents had been made. In others a careful examination of the abdomen with a trained eye and educated hand, would have made the diagnosis almost positive. However, in a certain percentage of cases, even after the most expert examination, both physical and laboratory, the diagnosis hangs in the balance for the time being. Did space permit, I might illustrate these different points by referring to actual cases seen in private and hospital practice.

Diagnosis.—The physician frankly admits that the cure of cancer of the stomach by medical means is absolutely impossible. The only hope for cure lies in the field of surgery. Consequently the chief ambition of the internist is to make an early diagnosis and then refer the patient for operation. Theoretically this sounds well, but practically results have not been encouraging. The technic of pylorotomies and resections has been developed remarkably and most patients recover from the operation if performed by a skillful surgeon. But the disease has not been entirely eradicated; in the majority of cases that come to operation there are already secondaries—or the incision has not gone beyond the cancerous tissue. Unfortunately, cancer of the stomach may have existed for some months even without symptoms. Do any of the modern gastric methods furnish us with means of making an early diagnosis? Before answering this question permit me to cite the results of some very careful analyses of stomach contents, in a number of cases of cancer of the stomach and pernicious anemia.

¹ Read before the Denver City and County Medical Society, November 17, 1903.

During the past six years, while a member of the Medical Staff of the University of Michigan, it was my duty during most of this period to make careful physical examinations of the "in" cases entering the medical clinic. Among these were between 40 and 50 cases of cancer of the stomach and esophagus, and nearly as many cases of pernicious anemia and large numbers of the different varieties of stomach diseases. Space will not permit of a detailed report, and therefore I shall confine my attention largely to a series of cases, hospital and private, which were examined and studied during the past year.

The analyses of the stomach contents were made by trained members of the medical staff or by myself and are as follows:

EXAMINATION OF STOMACH CONTENTS.

CANCER OF THE STOMACH.

1. Radtke: Granose test breakfast.
1 hour amount.....75 cc.
Free HCl.....0
Total acidity......85
Microscope—Many long (Oppler-Boas') bacilli.

1. Radtke: Granose test breakfast.
Free HCl.....0
Loosely combined HCl.....14
Organic acids and salts.....30

Total acidity.....44
Lactic acid, 5 to 1 part p.m.
Pepsinogen—No change in 9 hours.

Microscope—Many long bacilli.
1. Radtke: Boas' test meal.....40 cc.
Free HCl.....0
Lactic acid.....1% to .05%
Good pale yellow green (Strauss).
Washing showed corn which had been in the stomach for two days.

CANCER OF THE STOMACH.

1. Radtke: Boas' test meal.....17.5
Total acidity.....
Microscope shows long bacilli and yeast.

1. Radtke: Granose test breakfast.
Free HCl.....0
Loosely combined HCl.....7.5
Organic acids and salts.....60

Total acidity.....67.5
Pepsinogen—No change in several hours.
Microscope shows long, non-motile rods; yeast but no sarcinae.

2. Reeder: Boas' test meal.
Free HCl.....0
Many long bacilli.
Moderate excess of mucus.
Pepsinogen—No change in 10 hours. Tube may not have reached stomach. Obstruction two inches from white line. Infant's tube.

2. Reeder: Granose test breakfast.
Amount.....2 cc.
Free HCl.....0
Total acidity.....0

3. Lang: Granose.
1 hour.....25 cc.
Free HCl.....0
Total acidity.....22
Pepsinogen—1.8 mm. in 11 hours. Some long bacilli.

3. Lang: Granose.
Free HCl.....2
Loose combination HCl.....7
Organic acids and salts.....7

Total acidity.....16

PERNICIOUS ANEMIA.

1. Brunstetter: Granose breakfast.

Organic acids and salts.....6

Total acidity.....32

In the following cases of undoubted cancer of the stomach, we note the interesting finding of the presence of free hydrochloric acid in the stomach contents, varying from a slight hyperacidity in the cases of Mrs. Abendshine and Mr. Lang, to a moderate hypoacidity in several of the other patients.

Cases of cancer of the stomach, showing free hydrochloric acid in the stomach juice:

In the following cases of cancer of the stomach: Radtke, Reeder, Mersen, Van Dyke, Schmidt and Recklau, free hydrochloric acid was absent in one or more examinations or only showed a trace.

In all of the nine cases of pernicious anemia free hydrochloric acid was absent.

The conclusion to be drawn from these findings is that a persistent absence of free hydrochloric acid is more characteristic of pernicious anemia than it is of cancer of the stomach.

There can be no question about the correctness of the diagnoses in the cases cited. Cancer of the stomach was determined in practically all by the presence of a tumor and other classic signs of the disease or by exploratory operation. Pernicious anemia was proved by extremely careful blood counts, estimation of hemoglobin, differential counts and the finding of megaloblasts and normoblasts; and by the exclusions of conditions such as bleeding piles, intestinal parasites and other diseases, which might cause a severe secondary anemia.

An analysis of the stomach findings in the foregoing cases reveals the following important facts: In all of the patients with pernicious anemia there was a complete absence of free hydrochloric acid and likewise a

practical absence of loosely combined hydrochloric acid and lactic acid. Also an absence of the ferments, pepsin, pepsinogen and lab ferment when tested for. In other words, there was an achylia gastrica. Furthermore, in the vast majority of the cases of pernicious anemia, the motor power of the stomach was good, as we find very little evidence of retention and fermentation, the analyses showing, in most cases, an absence of yeast, sarcins, lactic acid, long bacilli and retained food.

In the cases of cancer of the stomach, several show a goodly amount of free hydrochloric acid, as before mentioned; most of them, a total acidity of some moment, but made up of loosely combined hydrochloric acid, and especially of organic acids. In practically all of the cases there was evidence of considerable stagnation and fermentation—such as retained food—long bacilli, sarcins and yeast.

In chronic atrophic gastritis there may occasionally be a dilation of the stomach, with signs of retention in addition to the absence of acids and ferments, as in the majority of cases of cancer of the stomach.

We may speak of two classes of atrophic gastritis, the one associated with pernicious anemia and the other in which the anemia has not developed. Why is there this difference? Is there a hemolysis in one and not in the other? Does the small intestine vicariously take up the work of the stomach in those cases in which a pernicious anemia does not develop and not in the others? Or is there something in the blood of these patients which resists the action of the toxins?

It may be that in some cases chronic atrophic gastritis has nothing to do with the development of pernicious anemia, but rather is the result of that disease.

Location of the Tumor.—A pyloric tumor is by no means always located in the pyloric region. As the result of gravity or traction this tumor may be located in almost any part of the abdomen from the left hypochondrium to the pelvis.

Symptoms are, of course, useful in assisting in the location of the newgrowth. The vomiting of large quantities of gastric contents, especially food which had been in the stomach a few days, the presence of a large swelling in the epigastrium, undergoing peristalsis and antiperistalsis, if associated with a mass located in the right hypochondrium or in any other part of the abdomen, moving down readily on deep breathing, or perhaps not moving at all, makes one almost positive that the pylorus is involved in the newgrowth. If there is no vomiting or evidence of retention, but a tumor is present in the pyloric region, we conclude that the mass involves the lesser curvature and extends close up to the pylorus, or that the pylorus is involved and the opening kept patent. To be positive which curvature is involved, lesser or greater, it is essential, especially in women, to distend the stomach.

We frequently find a growth just above the navel, in the region of the normal greater curvature, but on distention learn that this is the lesser curvature of a dislocated stomach. Inflation of the stomach is absolutely essential in deciding whether the anterior or the posterior wall is involved. If the latter, inflation will place a cushion of air in front of the tumor, so that it is not so readily felt, while if the former, it will make it more prominent.

The gastroduaphane is of very little use in this connection.

Treatment.—Medical treatment is at best only palliative. Surgical treatment in the vast majority of cases is the same, but in cases of pyloric stenosis the palliation is something remarkable. With extreme rarity radical operation effects a cure. I know of only one instance in which there was apparently a complete cure, and this was in a case of sarcoma of the pylorus.

Medically, a stomachic before meals, such as some preparation of condurango (wine or fluid extract), hydro-

chloric acid, and ferments after meals, with a carefully selected diet may be extremely useful for a varying period of time. If there is evidence of pyloric stenosis, with retention and fermentation, gastric lavage is absolutely essential for the patient's comfort. Röntgen ray treatment has proved disappointing in the treatment of patients with cancer of the stomach. Better still, if the patient's condition and the size and location of the growth will justify, is surgical intervention. The operation selected, whether a pylorectomy or a gastroenterostomy, will depend upon the findings after opening the abdomen. It is absolutely impossible to state with certainty beforehand which operation should be performed. If the growth is strictly limited to the pylorus, and not too large, if there are no important adhesions to neighboring viscera, if there is no secondary involvement of the liver, pancreas or lymphatic glands, and above all, if the patient's condition will justify it, the serious surgical procedure, pylorectomy should be performed. Otherwise the more simple, gastroenterostomy should be resorted to. The preference of the surgeon will decide between the McGraw elastic ligature and the Murphy button. The majority of the patients seen by me were operated upon either by Dr. Nancrede or Dr. Darling, and the McGraw elastic ligature was used.

I recall 3 or 4 pylorectomies in patients whom I had examined previous to operation.

The first patient, a woman in her thirties, had the typical signs and symptoms of pyloric stenosis. The tumor was large and it was necessary for the surgeon to resect about a third of the stomach. Recovery from the operation was rapid, all symptoms disappeared, the patient gained remarkably in weight, and strength, and general health. This happy condition of affairs continued for some months, but the patient finally died in about a year.

The second was a remarkable case, and has been reported by Professor Dock.

In making the physical examination I found the following condition: Patient, Mr. Williams, father of Dr. Williams, of the medical class of 1903, Michigan, came to the hospital 5 years ago. He was in a condition of extreme emaciation, weighing less than 100 pounds, normal weight about 145. He was not especially cachectic. His symptoms were those of pyloric stenosis. An easily palpable tumor about the size of a hen's egg was felt in the pyloric region. It descended readily on deep breathing, and could be held down during expiration. I do not recall the exact stomach findings, but the tentative diagnosis was carcinoma of the pylorus. Operation was advised. Dr. Nancrede resected the pylorus, the patient made an uneventful recovery. All symptoms of stenosis and dyspepsia disappeared. He was able to eat a large mixed diet, and in a few months his weight reached 150 pounds. This excellent condition has continued for over 5 years. I saw the patient last spring, and he was in the best of health.

Pathologic examination revealed the fact that the tumor was a sarcoma, an extremely rare newgrowth in this region. The radical cure proves that the entire growth was removed, and that there were no secondaries.

The third patient was operated upon by Dr. Darling, in July, 1903. F. C. Schmidt, of Niles, Michigan, butcher, aged 45, came to the hospital because of severe pains in his stomach after eating, and enlarged glands in the inguinal and femoral regions. The present trouble began about a year ago. Nearly every meal brought on distress. This would continue for $\frac{1}{2}$ to 1 hour. The pains have gradually grown worse, and he now suffers nearly all the time, but pain is most severe just after eating. Patient took to his bed about 3 months ago; at this time he had chills and fever. He would remain in bed for several days, then go to work for a few days. He had severe drenching sweats up to 10 days ago, since then no chills, fever, or night sweats.

During the past month the character of the pains has changed; after eating he now feels as if there was a large snake inside of his abdomen, moving round and round and turning over.

The patient was emaciated and cachectic, had lost 20 pounds in weight. In the vault of the mouth was a hard growth, which had been there for 15 years. There were also several enlarged glands in the inguinal and femoral regions.

Abdomen.—In the epigastrium a large swelling appeared and disappeared, suggesting a distended stomach undergoing peristaltic movements. At times the movements extend considerably below the navel, mostly to the left.

Palpation.—Half way between the navel and the margin of the ribs, just to the right of the mid-line, a distinct hard mass is felt. It descends on deep breathing. It can also be felt in the mid-line and is ridge-like. The outlines cannot be distinctly defined. Analysis of the stomach contents showed:

Free HCl.....	0
Loose combined HCl.....	20
Organic acids and salts.....	44
Total acidity.....	64

Pepsin and pepsinogen were practically negative in 22½ hours. Lactic acid gave a very strong test. Many long bacilli in large bundles; also budding yeast. No sarcins. No tissue bits. The patient's father died of cancer of the stomach at 63 and the mother of the same disease at 53.

A diagnosis of cancer of the lesser curvature in the neighborhood of the pylorus was made and operation advised.

Dr. Darling operated, and found a circumscribed growth just back of the pyloric ring. As it was fairly free from adhesions and no secondaries found, a pylorotomy was performed. The patient developed a phlebitis a few days after operation, otherwise his recovery was uninterrupted. In 2 weeks' time he was eating a large mixed diet.

I received the following letter from him, dated October 7, 1903: "I never felt better in my life. Am attending to my business every day. I have gained 25 pounds; never was heavier. As for symptoms, I have none. I am eating everything and have no bad effect."

Gastroenterostomies.—The majority of cases of pyloric cancer when referred to the surgeon are not suitable for resection. In this event most surgeons choose gastroenterostomy, a much easier and less dangerous operation. The relief from symptoms and the improvement may be just as marked as that experienced after pylorotomy. Naturally, the improvement is only temporary, from a few months to several years. Of the 6 or 8 patients whom I have seen, two died, and apparently without good reason. In 2 patients the operation was done to relieve extreme cases of gastropnoia with dilation. In one other case to relieve pyloric stenosis, due to adhesion of the gallbladder to the pylorus and perforation of the pylorus by a gallstone. The other patients had cancer of the pylorus.

REPORT OF FOUR INTERESTING CASES.

CASE I.—Street, aged 32, a clergyman, consulted me July 4, 1902. He had applied himself excessively during the past 4 years to evangelistic church work. He had suffered from constipation for 10 or 12 years and had taken laxatives for several years. His stomach had given trouble for 5 years, *i. e.*, gas, and belching. For 8 months he had vomited from 1 to 10 or 12 times a week, never in the morning, rarely in the afternoon, but usually after the evening meal. On one occasion 3 years ago he vomited 2 or 3 tablespoonfuls of material mixed with mucus, a little later a teaspoonful of bright red blood. He has lost greatly in weight and strength and has become very nervous. During this time he consulted several physicians, some men of prominence. The diagnosis of nervous prostration and nervous dyspepsia was made on each occasion, because of the history of overwork, his profession and the nervous symptoms. When the patient came to me it was only necessary to strip him and carefully inspect and palpate the abdomen, to make a diagnosis of dilated stomach with newgrowth in the pyloric region. The patient was emaciated, having fallen off from 168 to 137 pounds. He was a trifle cachectic. The examination of the chest was negative.

Examination of the abdomen revealed a dilated stomach, markedly distended with gas, and showing active peristalsis and antiperistalsis. The greater curvature was ½ inch below the navel. In the region of the pylorus was a hard mass the size of an egg, descending with deep breathing and capable of being held down during expiration. The stomach tube was immediately passed, and a large quantity of foul, fermenting material withdrawn. On standing there appeared an upper layer of frothy material an inch thick. Microscopic examination showed sarcins, yeast and large numbers of Oppler-Boas' bacilli.

Titration according to Töpfer's method gave:

Free HCl.....	10
Combined HCl.....	10
Organic acid and salts.....	60
Total acidity.....	80

The patient was placed on a selected diet and lavage. Six days later the stomach being washed out the night before, a Boas' test meal was given with the following analysis:

Free HCl.....	18-20
Combined HCl.....	8
Organic acids and acid salts.....	6
Total acidity.....	32-34

Two days later the patient was put into a hot bath at 110° for a more careful abdominal examination. In addition to the pyloric tumor, an elastic air cushion-like mass about the size of a coconut was felt in the right flank. It descended on deep breathing. During that night he had intense pain in this location. There was marked distension and very striking peri-

stalsis. This continued all the next day in spite of careful irrigation of the stomach and colon, on two occasions. It was relieved by hypodermic administration of morphin and atropin. Dr. Nancrede saw the patient in consultation and agreed upon the advisability of operation.

My diagnosis was dilated stomach, secondary to tumor of the pylorus. Because of the patient's age and the presence of a fair amount of hydrochloric acid, I felt that it was impossible to make a positive diagnosis of carcinoma. The history of having vomited a small amount of fresh blood several years before made ulcer with marked pyloric thickening a possibility. Benign tumor of the pylorus was also considered. The presence of sarcins, yeast, and especially long bacilli, made carcinoma a possibility. However, it was deemed necessary to perform an exploratory operation, with the idea of doing a gastroenteroenterostomy—with the McGraw elastic ligature—or whatever else seemed advisable after opening the abdomen.

The operation was satisfactorily performed, and a good result anticipated. But, contrary to expectations, the patient did not do well—vomiting soon set in and continued in spite of frequent stomach washings, till his death 3 days later. Evidently a vicious circle became established, in spite of efforts to guard against it by enteroenterostomy.

Autopsy revealed a scirrhus of the pylorus, producing marked stenosis. The cushion-like mass in the right flank was explained by the pressure of very strong bands of adhesion constricting a section of the intestines. It was noted with interest that the elastic ligature had only partly cut its way through.

The following case was of unusual interest because of the fact that all the patient's symptoms and signs were those of a typical case of advanced carcinoma of the stomach, but he had never been asked to remove his clothing by his physician. The abdomen had never been inspected or palpated.

CASE II.—J. B., a merchant, aged 58, complained of distress after eating. He induced vomiting in order to obtain relief; only twice did he vomit involuntarily. The vomitus was very sour. He had lost 34 pounds in weight, from 170 to 136, and had grown pale and weak. He was perfectly well up to 4 months ago. He had suffered from constipation for 4 months. He lived on soft-boiled eggs, toast, and rice. He ate greens for dinner and vomited them the next morning. He passed water frequently, getting up 2 or 3 times at night. Palpitation was noted.

The patient was distinctly cachectic, being pale and sallow. In the epigastrium was a large, hard, irregular mass, about the size of an orange, apparently involving the lesser curvature, and extending over to the pylorus. It descended on deep breathing. The stomach tube was passed, and a large quantity of foul-smelling material withdrawn. This was analyzed, and as I remember, showed an absence of free HCl. Good test for lactic acid and yeast and long bacilli. He was told (at his urgent request) that he had advanced carcinoma. He went to a sanatorium, was treated for a few weeks, returned home, and died in 3 or 4 months.

Rectal examination showed no involvement; liver was not enlarged; blood showed secondary anemia of 50% hemoglobin.

CASE III.—Mrs. H., aged 45, was seen in consultation. Her physician had discovered a mass in the abdomen, but was uncertain whether it was an enlarged spleen or omentum, etc., or abdominal aneurysm. She complained of daily vomiting, extreme weakness, and great loss of weight. She was emaciated cachectic, very pale and sallow. Abdominal examination: In the epigastrium over the abdominal aorta and pulsating with it was a mass the size of the fist. Side position caused the tumor to fall to one side of the aorta. The mass moved very little with respiration. The spleen and liver were not enlarged. Rectal examination was negative. The uterus and ovaries were in the posterior culdesac, but were not carcinomatous.

Analysis of stomach contents was not made, not being deemed necessary. The patient died in a few weeks. No autopsy allowed.

CASE IV.—Mrs. H., aged 68, proved very interesting because of the fact that a diagnosis of floating kidney had been made. Her appearance might easily have suggested chronic parenchymatous nephritis, as she was very pale and sallow, with edematous face and ankles, and a practical absence of any striking stomach symptoms.

Because of her mental condition and inability to speak English, it was impossible to obtain a satisfactory history. She had gradually failed, growing thin, and pale, and weak. She said that she had not vomited. Her son thought that she had vomited once or twice.

Examination of the abdomen showed on inspection marked distension except in the epigastrium. Palpation revealed a tumor about the size of the kidney in the right hypochondrium. It was very freely movable, could be pushed up under the ribs (a diagnosis of floating kidney had been made). On feeling of the mass it struck me that it was too irregular and nodular, and too far forward for the kidney. Likewise, when the patient was turned on her left side it moved over in the position of the stomach (a dislocated stomach). Later it could be felt as a rather long, hard mass, 3 in. by 4 in. by 1½ in., occupying apparently the lesser curvature of the dislocated stomach.

Autopsy proved this to be a scirrhus of the pylorus and lesser curvature having the size and shape of a kidney.

In conclusion, the association of a persistent absence of free HCl, the presence of lactic acid, long bacilli, yeast and retained food, with a tumor and cachexia, in the vast majority of cases, of course, means carcinoma. Even if a tumor is not detected, one is justified in making this diagnosis. The positive diagnosis of the case in its early stages is absolutely impossible. In an obscure digestive case which repeatedly shows an absence of free HCl, and in which pernicious anemia has been excluded by careful blood-examination, if the patient continues to grow worse under good treatment, an exploratory laparotomy should be urged by all means, for diagnostic, and if indicated, for therapeutic purposes.

It is natural to ask, of what value are the much-vaunted laboratory findings in the diagnosis of cancer of the stomach. It has been noted that all of the so-called classic laboratory evidence may be detected in other diseases. For instance, it is possible in a case of chronic atrophic gastritis with dilation, to find them all except the bits of carcinomatous tissue, *i. e.*, absence of free HCl and the ferments, and the presence of lactic acid, Oppler-Boas' bacilli, yeasts, and sarcins. Furthermore, we have seen that a small percentage of undoubted malignant cases furnish a fair amount of free hydrochloric acid. Our attention has also been drawn to the fact that if we were depending on the absence of free HCl in the stomach contents for a diagnosis of cancer of the stomach, many cases of pernicious anemia would be diagnosed as such.

The lesson to be learned is that laboratory diagnosis if incomplete and too much emphasized, may lead to unfortunate conclusions. It is the physician who takes a broad view of his cases from the standpoint of a careful history and physical examination and experience, combined with the assistance of laboratory findings, who will make the fewest errors in diagnosis. The younger medical generation is prone to emphasize too much the importance of laboratory work, while the older is likely to minimize its importance.

CONGENITAL INTRAUTERINE POLIOMYELITIS AND NEURITIS: THE QUESTION OF THEIR OCCURRENCE AND INFLUENCE UPON SO-CALLED CONGENITAL DEFORMITIES.*

BY

JOSEPH FRÄNKEL, M.D.,
of New York City.

Instructor in Nervous Diseases at Cornell University Medical College;
Attending Physician to the Montefiore Home.

AND

B. ONUF (ONUFROWICZ), M.D.,
of Sonyea, N. Y.

Pathologist to the Craig Colony; formerly Neurologist to St. Catherine's Hospital, and Consulting Neurologist to the Jewish
Dispensary, Brooklyn.

The following case of multiple deformities, which has already been the subject of a preliminary communication by Dr. George R. Elliott, at the meeting of the American Orthopedic Association, June 2, 1899,¹ suggests the inquiry as to the occurrence of anterior poliomyelitis and central neuritis as congenital conditions acquired during intrauterine life:

I. S., a girl, aged 4, became an inmate of the Montefiore Home September 22, 1895. The mother of the child was seen only once, and therefore numerous details of the history could not be ascertained with desirable accuracy, particularly details that suggested themselves after the case was studied for awhile. The father and mother of the child were not related by blood, and no evidence of hereditary defects was obtained.

The child was born naturally at full term, and was not asphyxiated. It is fairly certain that the condition of the extremities, for which relief was sought, was noticed immediately after birth. The child was breast and bottle fed. During

the first year convulsions are said to have occurred. Their nature and frequency are not ascertainable. At no time could the patient use upper or lower extremities well. She began to walk and talk at a natural age, although these functions were at no time normal. Occasionally the child complained of vague pain in the head and hands.

One and a half years ago an operation on the left foot (apparently osteotomy for club-foot) was performed in the Fifteenth Street Hospital.

During the patient's stay in the Montefiore Home from September 22, 1895, till June, 1897, when she died from a foudroyant malignant diphtheria, she was frequently and thoroughly examined by Drs. George R. Elliott, B. Sachs, Chas. Dana, V. P. Gibney, and by us. Different opinions were expressed about the nature of the condition. The results of the examinations mentioned are stated below:

Patient is fairly well nourished and a fairly well-developed child, being 84½ cm. in height and weighing 29½ pounds. The child shows normal cerebraction for its age, is usually in a happy frame of mind, although at times cranky. The externalization of the emotions is decidedly explosive and spasmodic. The examination of the vegetative organs is negative. Skin shows an extensive eczema capitis, and dependent thereon the cervical glands are enlarged.

The most pronounced features of the case are:

Motor disturbances of all four extremities, characterized chiefly as bilateral wrist-drop and drop-foot and disturbances of speech and of facial innervation, as described below. All cranial nerves are normal, excepting the seventh, and possibly the twelfth. The facial innervation is asymmetric, the face being drawn to the left side, especially when the patient laughs or cries. The tongue deviates markedly toward the left side. The speech shows marked dysarthric features.

Upper Extremities.—These are markedly tapering. There is considerable atrophy of the musculature of the forearm and more so of hands and fingers, so that the skin over the dorsal surface of hands and fingers is singularly baggy. Both hands are in position of wrist-drop. Over the right elbow there is an extensive scar, the result of an attempted operation. The upper extremities are loose and flabby. The passive excursions of both shoulders are free. The right elbow permits extension to a right angle only and the left to an angle of about 150°. Beyond this an insurmountable resistance is encountered. This resistance is evidently purely osteogen. The motor power of the forearm and hands is considerably diminished. The patient succeeds in extending the fingers, but very little, and the hands not at all. When asked to grasp an object, she takes it between the index and middle fingers, showing inability to adduct and abduct the thumb. The reflexes of the upper extremities are not elicitable.

Lower Extremities.—The lower extremities show the same markedly tapering appearance as the upper. Marked talipes equinovarus on both sides, particularly on the right side. The right lower extremity is longer than the left. The difference in length concerns the thighs and not the legs. There are no apparent atrophies. There are no muscular rigidities but the passive excursions of the left hip meet resistance. The motor power of the flexors of the leg and the extensors of the foot is considerably diminished in both extremities. A displacement of the right caput femoris is distinctly present. When the child is put in an erect posture and attempts to walk, two phenomena become apparent: Cock-step gait, and an intense lordosis of the lumbar column. Knee reflexes are present. Plantar reflex is normal. Achilles reflexes are not elicitable.

Electric Examination.—The flexors and extensors of the wrist do not respond to any electric stimulation. In some of the muscles of the lower extremities various phases of degenerative reaction are encountered.

Additional Clinical Data.—The patient was examined again on 3 further occasions, namely on December 17, 1896, on March 4, 1897, and for the last time on April, 1897, 2 months prior to her death. A careful comparison of the notes taken at these 3 examinations with those of the initial examination shows that the clinical picture remained practically unaltered during those 2 years with the exception that the patient's vocabulary increased and that her articulation became better although remaining still defective, the difficulty lying mostly in the pronunciation of the s's and t's and the speech being stammering. The condition being otherwise stationary as we have just pointed out, we shall give only such data of the subsequent history which serve to complete the first notes in some details.

Upper Extremities.—The abductor pollicis muscle acts well, the flexor pollicis not at all, the extensor pollicis very little, its action being confined to slight extension of the last phalanx of the thumb. Patient can spread the fingers and can flex the last 3 fingers in the phalangeal joints. The metacarpal bones are made out with great distinctness. The fingers are long and show a slight semicircular curve, with concavity to palmar surface, especially so the index and the third and fourth fingers. The wrist cannot be fully extended passively, owing to mechanical causes, while passive flexion can be pushed to such a degree as to bring the palmar surface of the hand in contact with the forearm. The power of active movements in the wrists is entirely gone, while pronation and supination and the movements of the elbow are limited.

Lower Extremities.—The movements (active and passive) of the hip and knee-joints are free, except that there is

* Read before the New York Neurological Society, November 5, 1903.

some resistance to full extension of the knee and that the excursions of the left hip are somewhat diminished. Voluntary movements of the ankles and toes are preserved to a slight extent.

Attempts were being made by Dr. Elliott to replace dislocation of the hip when the malignant diphtheria developed, which ended fatally after 24 hours.

ANATOMIC FINDINGS.

The autopsy was made by Dr. George R. Elliott. Unfortunately no general autopsy notes were taken, but the whole pelvis, with all its muscles and with the adjoining portion of the thighs, and the right forearm and hand, were removed. These 2 specimens were carefully studied by Dr. Elliott,¹ whose report we give herewith:

Right Forearm and Hand.—There is a subluxation of the head of the radius forward. The orbicular ligament is not rup-

Text Fig. 1.—Photograph of pelvis of patient, partially dissected, showing dislocated hip (left). (From Dr. Elliott's picture, published l. c.)

Text Fig. 2.—Photograph of plaster cast of portion of right forearm and hand; also radiograph of partially dissected right forearm and hand. (From Dr. Elliott's picture, published l. c.)

tured, but appears stretched, similar to that of the left subluxated hip to be mentioned later. The head of the radius rests upon the coronoid process of the ulna.

Muscles: Anterior Brachial Region, Superficial Layer.—Palmaris longus absent. This is frequently absent normally. Pronator radii teres, flexor carpi radialis, and flexor carpi ulnaris all fairly well developed. Flexor sublimis digitorum: The ulnar half of this muscle sending tendons to ring and little fingers is atrophic, but does not show fatty change; radial half of the muscle is composed of fat; apparently no muscular fibers remain. The original contour of this part of the muscle, now entirely fatty, is clearly defined.

Anterior Brachial Region; Deep Layer.—Flexor profundus digitorum is markedly atrophic and fatty. The fatty change increases from the ulnar to the radial side. The ulnar quarter sending its tendon to the ring finger is quite muscular, the second quarter less so, the third contains very few muscular fibers, while the fourth, or that connecting with the index finger, is almost entirely composed of fat.

Flexor longus pollicis is entirely converted into fat.

Pronator quadratus muscle is apparently normal.

Radial Region.—In place of the supinator longus is found nothing but a tendinous band. Extensor carpi radialis longior contains a few muscular fibers, but is chiefly tendinous.

Extensor carpi radialis brevior is fairly well developed.

Posterior Brachial Region; Superficial Layer.—Extensor communis digitorum, extensor carpi ulnaris, and extensor minimi digiti small, but present; no apparent fatty change.

Deep Layer.—Supinator brevis, extensor ossis metacarpi pollicis, extensor secundi internodii pollicis, and extensor indicis small, but absolutely free of fatty infiltration.

The extensor primi internodii is wanting.

In short, then, it is the flexor groups of muscles that we find converted into fat; while the extensors, on the contrary,

Text Fig. 3.—Drawing made from specimen as shown in photograph; showing site of dislocated left hip as compared with normal right hip; also fatty adductor group (left) contrasting with normal right. (From Dr. Elliott's specimen.)

show nothing of this wholesale fatty change, but exist as small, well-defined muscles.

Wrist.—Carpal bones present (see Text Fig. 2).

Hand.—Of the intrinsic muscles those of the thumb are chiefly at fault.

All the thumb muscles are absent except flexor brevis pollicis, which is fairly well developed. The muscles of the hypothenar eminence, on the contrary, are all preserved.

The lumbricales appear normal and well developed.

Dorsal interossei are present; first and second small, but showing no fatty change; third and fourth well developed.

There is a subluxation of the left hip upward and forward. Capsule is found intact and thickened, forming, together with a depression made in the ilium, a cavity for the head of the femur (see Text Fig. 4, accurately drawn).

The old acetabulum is well defined, measuring 2 cm. in diameter; that of the right, or normal, measures 2½ cm.

The old acetabular surface is covered with cartilage and its cavity filled largely with a very much hypertrophied ligamentum teres (see Text Fig. 5).

This ligamentum teres is 4 cm. long, $1\frac{1}{2}$ cm. wide, and 4 mm. thick. The head of the femur is reduced in size, measuring 2 cm. in diameter, covered with normal cartilage. The right

Text Fig. 4.—Accurate drawing of posterior view of pelvic specimen, showing different levels of the two femur heads, with muscular displacement, fatty gluteus minimus of left side and tendinous pyriformis muscle of left side (From Dr. Elliott's picture, published l. c.)

head is $2\frac{1}{2}$ cm. in diameter. Neck of femur is considerably shortened.

Both trochanters are well developed. Shaft of femur, at a distance of 6 cm. from small trochanter, measures 1 cm. in diameter; right, $1\frac{1}{2}$ cm.

Muscles of Pelvic Specimen: Anterior Surface of Right Side.—Psoas and iliacus apparently normal, so also the adductor longus, brevis and magnus.

Anterior Surface of Left Side.—The adductor longus and brevis are reduced to about one-fifth of the volume of the same muscles of the right side (compare Plate I Fig. 2 with Plate I Fig. 1). Between the adductor longus and brevis, on one hand, and the adductor magnus on the other, is a considerable mass of fat tissue, as there is also to the inner side of the adductor magnus (Plate I, Fig. 2). This fat tissue seems to have taken the place of the vanished muscular tissue. The psoas is well developed, though thinner than that of the other side, especially in its tendinous portion. The iliacus is markedly thinner than that of the other side, but otherwise of good appearance.

Text Fig. 5.—Accurate drawing of left dislocated hip of specimen, showing hypertrophied ligamentum teres, old well-preserved acetabular site, new acetabular site, and shortened femur neck. (From Dr. Elliott's picture, published l. c.)

Posterior Surface of Right Side.—The pyriformis, gemelli, obturator internus, quadratus femoris and the biceps and semitendinosus show a good appearance and apparently normal bulk. The right glutei, however, show rather much fat between

the muscular bundles, and are in general somewhat thin, especially the minimus.

Posterior Surface of Left Side.—The glutei show marked changes, consisting as they do of about as much fat and fibrous tissue as of muscular tissue; the fat and fibrous tissue being interspersed between the muscular bundles. The gluteus minimus seems to be entirely absent, but this might be erroneous, as it may not have been sufficiently separated from the medius in the dissection. The pyriformis is greatly reduced in bulk. The gemellus superior and the obturator internus seem to be of about the same size as those of the opposite side, and of normal appearance. The (left) gemellus inferior is somewhat smaller than the right one. The quadratus femoris is reduced to about a fourth of the bulk of the other side, being directed almost longitudinally instead of transversely. It has otherwise an almost normal appearance.

The biceps and semitendinosus are also reduced apparently to about one-third of the bulk of those of the other side.

This concludes Dr. Elliott's report on the macroscopic appearance of the 2 gross specimens (forearm, hand, and pelvic) which report we have taken partly from the publication quoted and partly from personal communications from him.

To sum up: Of the muscles forming part of the pelvic specimen on either side—namely, the adductors (longus, brevis, maximus), the ileopsoas, the glutei, the pyriformis, the

gemelli and obturators, the quadratus femoris, biceps, semitendinosus and semimembranosus—those showing the greatest changes macroscopically are: The left adductors, longus and brevis (reduced to about one-fifth in bulk); next, the left quadratus femoris (reduced to about one-fourth), the left biceps and semitendinosus (reduced to about one-third), the left pyriformis and iliacus (much reduced in bulk); also the left glutei, especially the minimus, (which are thinner and showing a great amount of interfascicular fat tissue); furthermore, the right glutei (the interfascicular fat of which is also increased at the expense of muscular tissue). Less changed are the left psoas and left gemellus inferior, showing only a reduction in bulk, while all other muscles of the pelvic specimen have an apparently normal gross appearance.

Text Fig. 6.—Right hip of specimen, showing normal ligamentum teres. (From Dr. Elliott's picture, published l. c.)

Microscopic Examination of Muscles.—The microscopic examination of muscles was confined to some muscles of the pelvic specimen of each side, which were chosen for comparison of the marked with the less marked, and of the fatty with the apparently only atrophic or fibrous changes. The muscles examined were the following:

1. The entire muscular mass—consisting of the adductors (longus, brevis, maximus)—and of the semimembranosus, semitendinosus, and biceps. Through this entire mass, at the level of the perineum, microscopic sections were made, the plane of which was vertical to the longitudinal axis of the thigh. Such sections were practised through said muscular mass of either side.

2. A piece of the gluteus medius plus minimus of either side, cut transversely.

3. A piece of the right and of the left psoas cut also transversely.

The examination extended not only to the muscle, but also to the condition of the intramuscular nerves and of the muscle spindles. For the sake of brevity, we omit the original detailed account of the findings, which, instead, may be summed up as follows:

1. Reduction in volume of certain muscles, chiefly of the left side, and especially the adductors, longus and brevis, the

quadratus femoris and pyriformis and iliacus of the left side; also of the glutei of both sides, but more of the left (see Plate I, compare Fig. 1 with Fig. 2).

Whether the muscular fibers themselves were reduced in caliber we did not ascertain. Hauck,² Schwalbe and Mayeda,³ J. Halban,⁴ and others have justly called attention to the great variation in the caliber of a muscular fiber in the same muscle according to the presence or absence of rigor mortis at the time when they are put into the preserving fluid and according to the kind and concentration of the preserving fluid itself. If these factors are unknown, no reliable data are obtainable, and this being so to a great extent in our case, we did not undertake any measurements of muscular fibers.

2. Increase of the perimuscular fat tissue around some muscles (the adductor group of the left thigh), of the intramuscular—i. e., interfascicular fat tissue in others (chiefly glutei of

Such areas of waxy degeneration are found in all the muscular sections examined by us except in those passing through the right psoas muscle. In one muscle (left psoas) also a muscle spindle shows the waxy degeneration.

6. Disintegration of muscle fiber in some muscles (glutei of left side, less those of right side), consisting either in entire defect of such, only the sarcolemma remaining, or in scarcity and irregular arrangement of the muscular fibrils with apparent loss of the interfibrillary substance. (Plate II, Fig. 2 at C, C, and D). The possibility of these changes being artefacts cannot be safely excluded however.

7. The apparently good preservation, if not increased amount of the muscle spindles in the affected muscles and the unusually large amount of muscular fibers found in the spindles, as many as 15 in a spindle (see Plate III, Fig. 1, showing a spindle with 15 muscle fibers (M) and a number of nerve

TABLE I.—SHOWING THE FINDINGS OF THE EXAMINED NERVE ROOTS.

Seg- ments.	Roots.			
	Left posterior.	Right posterior.	Left anterior.	Right anterior.
1 Cervical.	Apparently normal with the exception perhaps of a narrow peripheral zone.	(Altered.) Responding abnormally to Pal's stain (axis cylinders remain black), but interstitial tissue not thickened. (Bad differentiation, evidently too quickly differentiated.)	(Altered.) Apparently the entire root degenerated, but mostly the periphery. Interstitial tissue thickened.	
2 "	Decidedly normal excepting perhaps one or two small peripheral areas.	Normal.	Decidedly normal excepting perhaps a small area in the periphery.	
3 "	(Doubtful.) Seems more or less degenerated. Interstitial tissue not thickened. ¹	Normal.	Normal. ²	(Altered.) Apparently all degenerated. Thickening and dilatation of bloodvessels.
4 "	(Doubtful.) Only slightly altered if not normal.		(Altered.) Considerably degenerated. Interstitial tissue thickened.	Apparently normal.
5 "	Apparently normal.	(Altered.) On Pal sections one bundle bleached out, as if degenerated; in another bundle one area bleached out.	(Altered.) Responding abnormally to Pal's stain.	(Doubtful.) Only slightly altered, if so.
6 "	Normal.	Normal.	(Altered.) All degenerated. Interstitial tissue thickened.	(Altered.) All degenerated, to judge from the response to Pal's stain; but interstitial tissue not thickened.
7 "		(Doubtful.) More likely normal.		
8 "	Normal.	(Altered.) Two bundles normal but greatest part of the other three bundles responding abnormally to Pal's stain (axis cylinders remain black).		
Dorsal.	Normal except perhaps part of periphery in one bundle.	Evidently normal.	(Altered.) All degenerated. Scarcity of nerve fibers. Interstitial tissue and bloodvessels thickened.	(Altered.) Marked degeneration. Scarcity of nerve fibers. Thickening of bloodvessels.
1 Lumbar.	Normal.	Normal.	(Altered.) Degenerated. Responding reversely to Pal's stain. ³	(Altered.) Degenerated. Responding reversely to Pal's stain. Bloodvessels thickened. ³
2 "		(Altered.) Greater part normal. Some areas apparently altered.		(Altered.) All degenerated, responding reversely to Pal's stain. Interstitial tissue increased. ³
3 "	(Altered.) Some areas altered, responding abnormally to Pal's stain.			
4 "		(Altered.) One bundle normal, the other three responding reversely to Pal's stain. ³		
5 "	(Doubtful.) Part decidedly normal, and the remainder not typically degenerated, if at all.		(Altered.) Much degenerated (with the exception of a small area in each bundle). Interstitial tissue much increased. ³	(Altered.) All degenerated. Reversed response to Pal's stain. Bloodvessels and interstitial tissue thickened. ³
1 Sacral.	Apparently normal.	(Doubtful.) Part decidedly normal. The remainder also. Interstitial tissue not increased.		
2 "				
3 "	(Altered.) Altered, but not markedly.		(Altered.) Much degenerated, responding reversely to Pal's stain. Interstitial tissue increased. ³	
4 "				(Altered.) Altered, but not to much extent.

¹ It is possible that this root has been erroneously marked as the left posterior and that it is actually the left anterior.

² See what has been said under 1.

³ i. e., the axis cylinders being dark, the medullary sheaths white after the differentiation.

both sides, less the psoas of the right side) at the expense of muscular tissue.

3. Increase of the fibrous connective interstitial tissue between some muscles, chiefly between the adductor group and semimembranosus of the left side; hardly, however, if at all, in the muscles themselves.

4. Vascular changes (Plate II, Fig. 1—V.) consisting in the thickening of all walls and found chiefly between the adductor group and semimembranosus muscle of the left side, also in the glutei; less in the psoas muscle of the right side. It is chiefly the disproportion between the lumen and the thickness of the walls, at the expense of the former, that is abnormal.

5. Areas of waxy degeneration of muscles, found mostly in the neighborhood of large bloodvessels and of the connective tissue between the muscles (see Plate II, Fig. 1—W., taken from the point X of Plate I, Fig. 2).

fibers (N) from the right psoas muscle). Furthermore the waxy degeneration of one muscle spindle found in the left psoas muscle, all the other spindles found being apparently normal. The examination for spindles was not systematic enough, however, to allow far-reaching conclusions.

8. The presence of changes in the intramuscular and intermuscular nerve bundles of certain muscles, consisting in scarcity of nerve fibers, increase of the tissue between the fibers, and thickening of the perineurium. These changes, especially the scarcity of fibers, are most marked where the muscular atrophy was most pronounced, namely, in the section passing through the adductor group, biceps, semimembranosus and semitendinosus of the left thigh (see Plate II, Fig. 1, N—) but are seen also, although to less extent, in muscles which did not seem to be much changed (right psoas, for instance).

To this should be added that muscle spindles were nowhere found scattered in the midst of perimysial or intramuscular fat tissue, but always either directly surrounded by muscular tissue or bordering directly on such. Also note the fact that with one exception none of the muscle spindles was involved in the waxy degeneration or otherwise altered.

In comparing the gross findings in the muscles with the microscopic findings, it should be noted, that, what appeared grossly as a fibrous transformation of muscle, had no histologic equivalent, there being no increase of the intramuscular fibrous tissue in any muscle. Only the intermuscular fibrous tissue was increased in some regions.

Examination of the Nerve Roots.—Altogether 44 spinal nerve roots were examined microscopically. They were all either cervical, lumbar, or sacral, but not dorsal, with the exception of the first dorsal segment, of which latter all 4 roots were examined. Changes were found not only in many anterior roots, but also in a number of the posterior roots, as seen in the attached table. However, while the altered anterior roots, beside reacting abnormally towards the Wolters-Pal* stain, showed a notable increase of the interstitial tissue, and in some cases a great scarcity of fibers, the affected posterior roots showed only abnormal reaction to the said medullary stain, but not any hypertrophy of the interstitial tissue or scarcity of nerve fibers. It is needless to discuss the changes of each root in detail, since they are all tabulated in the attached table.

Plate III, Figure 2, depicts a cross section of the left anterior root of the sixth cervical nerve, which root is evidently much degenerated; for comparison see Plate III, Figure 3, showing the apparently normal posterior root of the same nerve. Both roots were stained after Wolters-Pal.

It must be said that on the whole the interpretation of the specimens was made difficult by the fact that they all had lain in alcohol for about 24 hours previous to being hardened in Mueller's fluid. Nevertheless, all having hardened alike, and many staining very well, the conclusion is pretty safely warranted that the pathologic changes quoted above were really present.

SPINAL CORD.

Gross Condition.—The brain and spinal cord, after the autopsy, were placed in alcohol of unknown concentration. About 24 hours afterward they appeared to be unusually soft. As the spinal cord and cerebral axis were to be examined for eventual tract degeneration, they were then put in Mueller's fluid, but the eighth cervical segment was placed in strong alcohol for examination with Nissl's method. This piece unfortunately dried out, owing to a crack in the vial containing it.

The gross findings of the spinal cord after the bichromate hardening were as follows: The whole cord is small, the length being 37 cm. from the oblongata to the filum terminale. The cervical and lumbar enlargements do not show the familiar intumescence, or such is at least badly developed, especially the lumbar enlargement. On sections through the upper cervical segments punctate depressions, usually 1 or 2, are seen about the middle of the anterior horn. The same condition is present in the lower cervical segments, but here the depressions lie more toward the lateral horn. The same condition exists also in the dorsal portion. In the upper lumbar region these depressions are multiple and scattered over the anterior and base of the posterior horn.

Microscopic Examination of the Spinal Cord.—The regions of the spinal cord subjected to microscopic examination were: All 8 cervical segments, the first, second, fourth, seventh, eighth, tenth, and twelfth dorsal and all lumbar and sacral segments.

Of each of these segments a continuous series of from 75 to 90 cross sections was made, the greater part of which were stained after van Gieson, but sections stained after Wolters-Pal were also taken from each of the examined segments. The total number of sections of the spinal cord amounted to 2,246.

We again refrain from recording here our original detailed notes on the changes found, as they would take too much space and needlessly tire the reader. The following summary will be sufficient:

1. A shrinkage of the nerve cells of the anterior horns in most levels of the spinal cord, but affecting some more and others less, some not at all or very slightly. Some cell groups are deeply affected, others slightly or not at all. In illustration of this unequal involvement of levels and cell groups, we refer to Table III, giving the condition of the anterior-horn groups of the lumbosacral region.

In view of the fact that certain muscles of the "pelvic specimen" on the left side were much more involved than those of the right side, as, for instance, the left adductor longus and brevis, quadratus femoris, biceps, and semitendinosus, it was expected to find some cell groups of the lumbar region particularly strongly involved on the left side and only slightly on the right, thus allowing some conclusions as to the representation of these muscles in certain cell groups. In this regard, however, we were disappointed, finding no distinct differences in the involvement of the cell groups of the two sides, except for the postposterolateral group, which seems more involved on the left side. Plate IV illustrates this cell group in the second sacral segment with its shrunken cells, Fig. 1

showing it under low magnifying power, and Fig. 2 under higher, while Fig. 3 shows one of the cells (C) of Fig. 2 under immersion.

The failure of finding otherwise any marked differences in the involvement of the cell groups of the two sides may be accounted for by the fact that no unbroken series of sections was made through the lumbosacral region, but only a consecutive series of from 75 sections to 90 sections taken from each segment.

Moreover, as only part of the muscles was examined, the topic relation between spinal and muscular changes could not be definitely established. We note, nevertheless, the apparent intactness of the posteromesial cell group of the sacral region, which in view of the preservation of the function of the vesical and the rectal sphincters, does not at least contradict the view promulgated by one of us (Onuf) that this cell group contains the nucleus for the said sphincter muscles.

2. Shrinkage of the cells of Clarke's columns on certain levels, as well as of cells of the lateral horn and of the zone between the bases of the anterior and posterior horns. On most levels, however, Clarke's columns, as well as the cells of the

The above table represents the normal distribution and relative size of the anterior-horn groups of nerve cells in the various segments of the lumbar and sacral regions in man. The sizes given are not based on a count of the nerve cells, but only on a rough estimate from serial study.

other formations just mentioned, were intact, contrasting singularly with the shrunken anterior horn cells.

3. Cavities in certain regions of the gray matter, much less in the white. These cavities are mostly of elongated shape and often with a bloodvessel in the center. They show usually fairly smooth margins and have no epithelial lining. In some regions, especially some cervical segments, they are so numerous in the gray matter as to give the latter a riddled appearance.

This is illustrated in Plate V, Fig. 1, depicting a cross section of the eighth cervical segment, in which "C" represents the cavities.

The possibility of these cavities being artefacts cannot be positively gainsaid.

4. Vascular changes, found particularly in the sacral region, especially the first and second segment near the central canal. Here the sections show groups of several transversely cut vessels lying close to each other, and the whole angioma-like group being surrounded by a smaller or larger mass of granular exudate. (See Plate VI, Figs. 1 and 2.)

* Modification of the Weigert stain.

5. Presence at certain levels (especially sixth and seventh cervical and second lumbar) of slender, elongated, almost vermiform cells with corkscrew-wound processes, appearing like incompletely developed cells. These cell changes are probably secondary to the shrinkage of the anterior horn cells and are much less extensive than the latter.

6. Proliferation of the ependyma of the central canal in certain regions, particularly the sacral. This is of so frequent occurrence that it requires no further discussion.

7. Changes of the white matter, particularly in the region of the pyramidal tracts, direct cerebellar tracts, and Gowers' columns of the cervical region. These changes look much like degenerations, but can be followed only for a short distance upward and downward and are more likely artefacts than actual degenerations.

In conclusion of the remarks on the spinal cord, we may say also that possibly, and even probably, part of the shrinkage of the anterior horn cells is artificial, but that a good portion of it is pathologic, cannot be doubted in view of the absence of this shrinkage in the cranial nerve nuclei (with a slight and explainable exception), notwithstanding the fact that the cerebral axis practically underwent the same hardening proc-

3. Upper part of the pons and velum medullare anterius up to just below the decussation of the fourth nerve.

4. Corpora quadrigemina, posteriora and anteriora.

These 4 portions were hardened in Mueller's fluid and cut serially. At most levels every fifth section, at others only every tenth section was preserved.

Naturally the series through the cerebral axis contains considerable gaps at the points at which it was divided as above mentioned, since owing to irregularities of the cut surfaces and incomplete parallelism of the same, a considerable portion of each block became lost.

Medulla oblongata and pons up to level of the facial nerve: At the lower levels of the pyramidal decussation there is marked shrinkage of the anterior-horn cells throughout the horn. A riddled appearance similar to that of the upper cervical region is seen in the lower part of the medulla oblongata, affecting both the white and gray matter—mostly the gray, however, and reaching up to the pyramidal decussation, being practically gone in the region of the inferior olivary bodies. The cavities are rather small, but numerous and frequently perivascular.

The proximal region of the medulla oblongata and the

TABLE III.—SHOWING THE CONDITION OF THE ANTERIOR-HORN GROUPS OF THE LUMBOSACRAL REGION¹ IN OUR CASE.

Level of spinal cord.	Mesial.		Anterolateral and group X.		Posterolateral.	Postposterolateral.	Central and middle.	
	Anteromesial.	Posteromesial.	Anterolateral.	Group X.			Central.	Middle.
I. Lumbar segment.	Apparently normal.	Apparently normal.	Apparently normal.	Apparently normal.	Apparently normal.
II. Lumbar segment.	Perhaps partly atrophic.	Evidently partly atrophic.	?	?
III. Lumbar segment.	Very slightly atrophic, if at all.	Perhaps partly atrophic.	Very slightly atrophic, if at all.
IV. Lumbar segment.	Most cells are shrunk.	Most cells are shrunk.	Apparently more atrophic than normal cells.	Probably not atrophic.	Apparently more atrophic than normal cells.	Much artificial shrinkage in this segment, making interpretation quite difficult.
V. Lumbar segment.	Decidedly partial atrophy; but apparently more normal than atrophic cells.	Decidedly partial atrophy; but apparently more normal than atrophic cells.	Atrophy perhaps slightly less than in the anterolateral and posterolateral groups.
I. Sacral segment.	Part of cells decidedly atrophic, others decidedly normal. In the proximal slides apparently more normal than atrophic cells; in the distal slides vice versa.	Same condition as in anterolateral group of same segment.	Decidedly atrophic.	Apparently normal.
II. Sacral segment.	Apparently normal.	Apparently normal.	Much atrophic.	Much atrophic, apparently most of all; more on one side than on the other.	Apparently normal.
III. Sacral segment.	Apparently normal.	Apparently normal.	Same condition as in II, sacral segment.
IV or V. Sacral segment.	Anterior-horn groups are practically gone here normally.							

Changes apparently about the same on both sides in all groups except the postposterolateral, which seems more atrophic on one side.

¹For the nomenclature of the cell groups, compare with Table II. (The latter is taken from B. Onuf's article: "On the Arrangement and Function of the Cell Groups of the Sacral Region of the Spinal Cord in Man," Archives of Neurology and Psychopathology, Vol. iii, No. 3, page 397, 1900. See also abstract on same subject in Journal of Nervous and Mental Diseases, Vol. xxvi, page 438, 1899.)

esses as the spinal cord, being put in alcohol at the same time and left in it for the same length of time, previous to hardening in Mueller's fluid.

Examination of the Brain: 1. *Cerebral Axis.**—The entire brain had been put in alcohol of the same (unknown) concentration as had been used for the spinal cord and was left therein for about 24 hours—that is, just as long as the spinal cord. Pieces of cerebral and cerebellar cortex were then removed for examination after Nissl, while the cerebral axis was cut off from the hemisphere at the uppermost level of each peduncle, and was (after removal of the cerebellum) severed transversely into 4 contiguous portions—namely:

1. Lower part of the oblongata up to about the middle levels of the pyramidal decussation.
2. Upper part of the oblongata and lower part of the pons up to the level of the sixth root.

*By cerebral axis we designate what the Germans call "Hirnstamm," i. e., that part of the brain which consists of the oblongata, pons, corpora quadrigemina, basal ganglia and insula, or in other words, all that remains of the brain after removal of the cerebellum and of the cerebral pallium (hemispheres).

lower part of the pons up to the facial root show rather numerous vascular changes. They are apparently of 2 kinds—old ones and recent ones. The old ones consist in thickenings of the bloodvessel walls, chiefly the muscularis and adventitia. The recent ones are characterized by the presence of a perivascular exudate, which in some places is of a granular character, appearing like detritus, while in others it is formed partly of this granular detritus-like mass, for the most part, however, of what seems to be red blood cells. Such recent changes are well illustrated in Plate VII, Fig. 1, which shows a bloodvessel presenting marked infiltration of its walls with round cells (r) and surrounded by a granular exudate (E).

Both the old and recent changes are found in different regions, but favoring, perhaps, mostly the neighborhood of the raphe and the middle cerebellar peduncle. The exudative changes seem, on the whole, more numerous than the old ones.

Region of corpora quadrigemina, velum medullare anterius and pons upward of the facial root:

These regions show some vascular changes, apparently mostly not recent ones, but such old ones as have been described for the upper part of the oblongata and lower part of the pons.

They are comparatively very slight, and much less numerous here than there.

Nuclei of the motor cranial nerves:

The nucleus of the twelfth nerve shows shrinkage of most of the cells in its mesial part on both sides, while most of those of its lateral half appear normal.

The nuclei of the third, fourth, seventh, ninth, and tenth nerves and nucleus ambiguus, also that of the sixth and fifth nerves appear quite normal. It is somewhat difficult to judge of the motor nucleus of the fifth as the series of this nucleus is rather defective, but where it is seen its cells look normal.

The nucleus of the eleventh nerve we do not discuss here, as it properly belongs to the cervical region. Of the twelfth nucleus, part of the cells, especially in the mesial portion, look decidedly shrunk on both sides, while the lateral ones appear for the most part normal. It is true that there are considerable gaps in some of the series, especially of the twelfth nucleus, which makes it rather difficult to judge. Yet the fact seems remarkable that aside from the hypoglossal nucleus the cells of all the cranial motor nuclei so far as seen, appear to be normal. This is interesting because clinically all cranial motor nerves, with the exception of the twelfth and seventh, appeared to be normal, and because of the fact pointed out already, that the cerebral axis had practically been hardened in the same manner as the spinal cord, and ought, therefore, also to have shown extensive cell shrinkage if such had been artefact.

More difficult is it to explain the affection of the left seventh nerve observed clinically to which apparently no anatomic lesion of the seventh nucleus corresponded. But it is true that the series through the seventh nucleus was rather defective, and so eventually diseased portions of the nucleus may have escaped notice.

We must not omit to mention that nowhere in the cerebral axis could any tract degeneration be found. It might be objected that the cerebral axis had lain in alcohol for 24 hours before hardening in Mueller's fluid, and that this would spoil it for the Weigert stain, but as a matter of fact, the latter stain succeeded very well, and the said objection can therefore not be upheld.

Diagrammatic chart, showing the findings of all the examined pieces of cerebral cortex of the left hemisphere, tabulated in graphic form. The ciphers 110, 111, 112, 113, etc., are the numbers of the specimens as they were registered in the catalogue of the Pathological Institute of the New York State Hospital. 110, changes, if present, are very slight, affecting possibly some of the pyramidal cells; 111, possibly some cells of the polymorphous layer changed; 112, changes in a fair number of the large pyramidal cells and in a considerable number of the polymorphous cells, mostly in the axial part of the convolution; 113, a small number of the polymorphous cells and still fewer large pyramidal cells are changed; 114, very few cells (large pyramidal) are changed, if any at all; 115, very few cells (large pyramidal), if any at all, show changes; 116, normal; 117, changes in a few of the large and middle-sized pyramidal cells; 118, very marked changes throughout the thickness of the layer of pyramidal cells, small and large, but almost only in the axial part of the convolution; 119, changes in many large pyramidal cells and in part of the polymorphous cells; 120, apparently normal; 121, apparently normal; 122, apparently entirely normal. • normal; • doubtful; • changes slight; • changes well marked; • changes very marked.

2. *Cerebral Cortex.*—We mention once more that after the brain had been lying in alcohol of unknown concentration (received by us in this manner) and showing then a suspiciously soft consistency, pieces of cerebral cortex were

removed, mainly from the motor region, but also from others (see the appended chart) and put in absolute alcohol. They were then prepared as required for paraffin drenching, cut, and stained after Nissl. The child having died of a phagedenic form of diphtheria, decomposition of the body was naturally favored and, moreover, the autopsy occurred in summer, about 12 hours after death. Our expectations regarding the availability of the material for microscopic examination, did, there-

Plate I.

fore, not run very high. The latter showed, nevertheless, that the state of preservation was much better than we dared to hope, yet not good enough to allow judging of the finer structure of the cells as revealed by the Nissl method. The differentiation between stained and unstained substance of the cell body was wiped out to a considerable extent, and, in view of what has been said, it would be hazardous to assert in how far this condition was due to, or contributed in, by the influence of the diphtheric poisoning. Evidences were found that some of it was undoubtedly due to postmortem changes.

Instead of reporting the detailed findings in the cerebral cortex, we refer to the appended chart in which the results have been graphically represented. It is seen there that altogether 13 different regions of the left hemisphere were examined. The black, circular spots denote changes, the degree of which is expressed by the size of the spot, while circular spots with a dot in the center denote normal findings.

A look at the 3 figures of this chart immediately elucidates 1 point, namely that whatever cortical changes are present, are not general, but confined to what we were used to call the motor region, namely the 2 central convolutions and the paracentral lobe. In all other cortical regions examined, no changes were found.

We have, therefore, to deal with a localized and not with a general cortical affection. Again in the "motor" region itself not all places are equally affected, but some more, others less, and of others it is doubtful whether they are affected at all.

The changes are apparently confined to the nerve cells and do not affect the interstitial tissue. No proliferation of neuroglia nuclei is seen, nor are there apparently any vascular changes. As to the nature* of the nerve-cell changes, such are either of the atrophic kind or the cells appear to have bizarre, undeveloped, "embryonic" shape. The cells involved are the pyramidal cells, chiefly the larger ones, and the cells of the polymorphous layer. In some regions almost only the axial part of the convolution contains the altered cells. (See chart.)

Plate VII, Fig. 3, illustrates some of these altered cells. The cell agglomeration depicted in the figure is taken from a section passing through the upper end of the posterior central convolution. The size and location of this cell agglomeration with relation to the whole convolution is indicated by the spot X of Fig. 2 of the same plate. In that figure the part marked // // // // // denotes the molecular layer of the convolution (Mol.), while the part marked Med. represents its medullary layer.

3. *Cerebellar Cortex.*—The piece of cerebellar cortex examined by us with the Nissl method presented nothing abnormal as far as we could judge, or at least we did not feel justified to consider as pathologic whatever alterations seemed present.

EPICRISIS.

In attempting to interpret the case the following views must be discussed:

*That the question of the presence or absence of changes in the finer cell structure must be left undecided, has been explained on p. 100.

1. The view of the peripheral origin of the disease, according to which the deformities and muscular changes are the primary cause and the spinal changes secondary to these.

2. The view of the central origin of the disease, which considers either spinal or neuritic changes as the primary cause and the muscular and skeleton changes as the secondary.

In discussing the view of the peripheral origin of the disease first one theory ought to be considered, namely, that which sees the primary cause in abnormalities of development of the skeleton, due to such prenatal causes as lack of amniotic fluid, intrauterine pressure from other causes, or intrauterine traumatism. This theory which, as Young⁵ says, is as old as medicine, but which

flexion of the wrist, this would by no means explain why, for instance, the radial half of the flexor digitorum profundus was entirely converted into fat, while the other half was only slightly changed, as has already been called attention to by Dr. Elliott in his above quoted article. Moreover, the condition of the carpal bones was not such at all, as to prevent muscular activity.

More reasons could still be adduced in contradiction of the skeleton theory, but those mentioned are sufficiently strong to disprove them.

Of other possibilities in the line of a peripheral origin we should mention:

1. Primary muscular dystrophy of the atrophic type.
2. Polymyositis.

To the first of these (namely, the dystrophy) the

Fig. 1

Fig. 2

Plate II.

Fig. 1.—Showing a small portion of the left adductor magnus muscle taken from the point X, of Plate I, Fig. 2; it shows areas of waxy degeneration of muscles (W), also two thickened bloodvessels (V) and a degenerated nerve bundle (N) with apparently only four nerve fibers left. M, normal muscular fibers. Fig. 2.—Portion of the left gluteus medius and minimus muscle showing disintegration (pathologic or artefact?) of some fibers (C, C, D); in D the fibrillas are almost entirely gone and the sarcolemma as depicted; oil immersion, Leitz, ocul. 1, objective 1/4 in.; picture taken from slide 718-74, 1/1 of the Pathological Institute.

found strong support chiefly by Cruveilhier, Roser and Luecke⁶ was put forth to explain congenital dislocation of the hip.

The theory of intrauterine traumatism can probably be easily disposed of, in view of the fact that the 2 dislocations namely of the right radius and left hip, which alone could be explained on a traumatic basis, were not attended by a break of the capsule. They could therefore hardly explain the deep muscular changes found. Even if these changes were considered as due to inactivity, they could not be accounted for by the subluxation, since such subluxation would not be apt to cause serious inactivity, such as would lead to the muscular degeneration found. Moreover, such a traumatic theory would by no means explain the deformities and paralytic symptoms of the foot and hand, *i. e.*, the double wrist-drop and drop-foot.

Again the theory of maldevelopment of muscles and skeleton from intrauterine pressure, or faulty position, could not account for the distribution of the muscular changes. If, for instance, the wrist-drop was due to changes in the carpal bones, preventing passive or active

clinical history is absolutely opposed, and it need not, therefore, be further considered.

The second possibility, namely, that of a polymyositis, is made extremely improbable by the anatomic findings.

We should in such cases expect to find evidence of focal muscular lesions, and the residues of such would be most likely extensive thickening of the fibrous connective tissue, scattered here and there within the muscle tissue. This was by no means the case. Whatever hypertrophy of fibrous connective tissue was present, affected the tissue between muscles, and not within the muscles. Moreover, the large number of muscle spindles found in the atrophied muscles speaks much more in favor of a degenerative than of an inflammatory origin of the muscular alterations, if the fairly well-adopted view is acknowledged of the sensory function of the muscle spindles.

One is therefore urged to look to changes in the peripheral nerves, or to spinal changes, as the primary cause of the muscular condition.

As to the peripheral nerves, such were not examined.

Having lain in formalin for a long time, they did not appear fit for examination for degenerative changes. Only the intramuscular nerves were seen, and these in many muscles presented considerable atrophic changes.

Plate III.

Fig. 1.—Muscle spindle from the right psoas, with fifteen muscular fibers (M) and a number of transversely cut nerve fibers (N); drawn from specimen No. 718-76, 1/2; Leitz, ocul. 1, with objective Zeiss A.A. Fig. 2.—Cross section of the left anterior root of the sixth cervical nerve, evidently much degenerated; Wolters-Pal stain; the medullary sheaths appear white, the axis cylinders black, instead of vice versa, as should be normally; drawn from specimen No. 118-47, 5/2; Leitz, ocul. 1, with Zeiss objective A.A. Fig. 3.—Posterior root of the same nerve as Fig. 2, stained in the same manner, and having a normal appearance; drawn from specimen No. 718-47, 6/1; Leitz, ocul. 1, with Zeiss objective A.A.

However, in view of the fact that the nerve trunks, such as the sciatic, were not histologically investigated, our judgment in this regard must be kept in abeyance.

Coming now to the spinal changes, one might think in the first place of an affection of the nerve roots, communicated, for instance, from a meningitic process. There was no pathologic evidence in favor of such view, and it may, therefore, be dismissed. The root changes must then be explained as secondary, *i. e.*, degenerative.

It remains, then, to assume an affection of the anterior horn of the spinal cord.

We cannot here discuss all the possibilities, but can touch only on the principal points.

In the first place, the theory of an agenesis of the spinal cord cannot be held up as the histologic evidence is in contradiction with such agenesis.

Progressive muscular atrophy and amyotrophic lateral sclerosis can be excluded both from the history and the findings. Syringomyelia is also excluded by the findings.

A myelitis affecting the anterior horns in addition to other regions of the spinal cord was a possibility seriously to be considered. However, if any myelitis was present it apparently did not to any extent reach beyond the gray matter. The changes that were found, certainly chiefly affected the anterior horns, so that if a myelitis did exist, it mainly was a poliomyelitis. Since, however, the changes consisted chiefly in the shrinkage of cells and no marked evidences of a past inflammatory process were found, it stands to question whether it would not be more appropriate to consider the cell shrinkage as the outcome of a past central neuritis, that is, a neuritis such, for in-

stance, as we find it, in lead neuritis, where the fundamental pathologic alterations must be sought for in a parenchymatous affection of the anterior-horn cells.

Weighing all the evidence, in conjunction with the clinical history, our conclusion is indeed that in the case of congenital deformities reported by us, the primary cause of the muscular changes, and incidentally also of the deformities, is either a poliomyelitis or a central neuritis of prenatal origin.

Such conception would fully explain the muscular changes, and the skeletal deformities could again be easily accounted for, as induced by the muscular alterations. This has particular reference to the dislocation of the hip, which can be best explained on the theory of changed dynamics of the hip-joint. The adductors, which in our case were markedly changed, would under normal circumstances help to press the head of the femur outward and downward and thus, with the other muscles acting as antagonists, keep the femur head in position. Loss of the adductor action by taking away the resistance offered by these muscles would then naturally give the other muscles full sway, and the head of the femur would be dislocated in the direction of the least muscular resistance, namely, upward and inward.

This is confirmed by the fact that the femur is dislocated upward and inward.

That the cortical changes were secondary to the spinal changes was made very probable by the fact that they affected only the motor region and certain parts of it.

Neither the cerebral cortex, nor the spinal cord was examined systematically enough to allow quite definite conclusions as to the correspondence between the intensity of the cortical changes and that of the spinal anterior-horn changes. On the whole, however, the mutual relation and dependency between the spinal and cortical cellular changes were pretty evident, and as the cortical changes were much less marked than the spinal ones, we are justified in consider-

Plate IV.

Fig. 1.—Shows the post-posterolateral group of the second sacral segment, in our case; the territory of the group appears lessened and its cells shrunk; drawn from specimen No. 718-228, 2/1.9. ing them as secondary to the former. The possibility of such occurrence is shown by the fact that in cases of amputation of long standing, atrophic changes in the central convolutions have been known to occur. Such

secondary cortical changes would be still more likely to arise when the primary disease giving rise to them, namely, an affection of the anterior-horn cells of the

spinal cord, started in at such an early period, *i. e.*, pre-natally, as was the case in our patient.

In searching about 30 textbooks on nervous diseases for data regarding congenital anterior poliomyelitis we struck only one giving information on this point, namely, Dana's, in which we found this statement: "It (meaning acute anterior poliomyelitis) may be congenital, *i. e.*, occur in intra-uterine life (Sinkler)." No other reference is given, but we were fortunate enough to find, nevertheless, the publication of Wharton Sinkler to which Dana refers, namely: "On the Palsies of Children" in *American Journal of the Medical Sciences*, Vol. lxix, p. 348, 1875.

We quote literally the entire passage of Sinkler's paper to which Dana evidently has reference.

Of the 2 cases which I have called congenital paralysis, one was a child in whom there was complete palsy of the right arm. The mother stated that at birth the right arm was shrunk, and not more than one half the size of the left. The child was delivered by forceps, but it is not likely that these

were the cause of the paralysis, for there was no sign of external injury, and when the patient was seen by me there was no contraction of the flexors in the affected limb. Moreover, the

Fig. 1.—Shows the vascular, angioma-like changes in the sacral region (II sacral) near the central canal in our case, as described in the text; A, B, C, D, E, bloodvessels; drawn from specimen 718-228, 1/11. Fig. 2.—In this figure the spot in the center represents the region illustrated in Fig. 1, giving its relative size and location.

paralysis and atrophy were evidently from one and the same cause. The muscles of the arm were all easily moved by the faradic current, and by the use of this agent there was a great

Plate VII.

Fig. 1.—Illustrates a bloodvessel of the cerebral axis, the walls of which are infiltrated with round cells (T) and which is surrounded by a granular exudate (E); drawn from specimen No. 718-121, 1/15.2. Fig. 2.—Somewhat diagrammatic figure; representing a section through a section through the upper end of the posterior central convolution (in our case), drawn with the purpose of giving the size and location (X) of the region depicted in Fig. 3. Fig. 3.—Depicts an agglomeration of cells from the spot X of Fig. 2; some of the cells show the bizarre, elongated, apparently shrunk or undeveloped form described in the text; drawn from specimen No. 718-18, 1/4.4; Leitz, ocul. 1, oil immersion 1/4 in.

gain in power. The other case was one of paralysis of the right leg, which had existed from birth.

Of the second of these cases not much can be made,

as details are wanting, but the first one certainly gives a clinical picture corresponding closely to that of a poliomyelitis, although an obstetric paralysis cannot be quite safely excluded, even if it is not very probable. There was no postmortem evidence in this case to confirm the diagnosis.

As to congenital neuritis, our search in the same 30 textbooks of nervous diseases also proved futile with one exception. In Oppenheim's "Lehrbuch der Nervenkrankheiten," second edition, 1898, we find the following statement, which we render here in English: "Of interest is the fact that lead-poisoning can produce morbid conditions also in the offspring. A lead palsy which could hardly have been acquired otherwise than by way of hereditary transmission (Vererbung), I had opportunity to see in a case (Fig. 164). It affected the radial and peroneal muscles in a typical manner."

These are the only data from literature in support of our interpretation of our case as either prenatal, *i. e.*, intrauterine acute anterior poliomyelitis, or a congenital "central" polyneuritis.

These 2 conditions—acute anterior poliomyelitis and "central" neuritis—are indeed evidently closely allied, since lead, which usually causes a central neuritis, also may cause an anatomic process identical with poliomyelitis, as one of us (Onuf) had occasion to prove in a case of undoubtedly lead palsy examined postmortem.

Taken all in all, then, our case stands almost unique in the literature, and we only regret the unpropitiousness of circumstances, death by a foudroyant infectious disease, autopsy in midsummer, and about 12 hours after death, deficient preservation of the specimens before they reached our hands, and such more, which had brought the autoptic material to such a condition as to make its histologic interpretation very difficult. This was a reason more to abbreviate our report, by leaving out a great number of the original descriptive notes, making it thus a little more palatable to the reader. We wish to add one word, however, concerning the "recent" vascular changes found in the cerebral axis (see p. 102). These we probably can rightfully attribute to the diphtheric poisoning or infection.

How carefully the case was investigated anatomically is evidenced from the fact that about 5,500 microscopic sections were made, stained, and mounted, and most of them examined.

We cannot close this report without expressing our gratitude to Dr. Louis Lichtschein for the very material help given us in the preparation of the microscopic specimens.

MALARIA FOLLOWED BY INTERSTITIAL NEPHRITIS AND PERIPHERAL NEURITIS.

BY

OTTO LERCH, A.M., M.D., Ph.D.,
of New Orleans, La.

Professor of Clinical Diagnosis, New Orleans Polyclinic.

In a country like this, where malaria prevails, any complication of, or sequence following this disease, must be of interest to the practitioner.

The following case of peripheral neuritis and interstitial nephritis following malaria was observed in the Charity Hospital.

The patient entered my ward November 19, 1902. He was born 56 years ago, in Fort Worth, which was his place of residence until he came, a few months ago, to Louisiana. He states that his father died at the age of 76; his mother at the age of 65, from heart disease. He has 2 brothers and 2 sisters living and healthy. He has passed through the diseases of childhood, measles, mumps, whoopingcough, and contracted malaria when 9 years old. He denies any venereal disease, and claims to have been well, up to his present trouble, which began October 14. He was working in the field in the sun, when at about noon he felt "that something was passing through his head that knocked him down." He did not lose consciousness, but remembers that he was picked up and carried home. For 3 weeks he suffered with a high, continuous fever, for which he was treated by local physicians. He then came to New Orleans and entered the hospital. He complains of excessive weakness, loss of appetite and sleep; numbness of left hand and outer portion of left thigh, formication over left forearm and fingers of left hand; states that he has a sensation as if his thigh was covered with felt; his bowels are regular, and he has full control over the bladder and rectum; urinates frequently at night. Since he was first taken sick he has suffered from severe frontal headaches, which he says come on at irregular intervals, lasting for hours and for days. The patient is a confectioner by trade; has used whisky and beer very moderately, and smokes a pipe as a rule. He measures 5 feet 6 inches, and his average weight has been 120 pounds. He weighed, on entering the hospital, 115 pounds. He is of a deadly pallor, and his skin is cold and clammy. There is some edema of the feet and ankles and puffiness of the eyelids. The lungs are normal, the superficial arteries are in fair condition; the radial pulse is 80, regular and empty; heart dulness is normal, sounds are pure and weak; the liver is enlarged, the lower border protrudes below the border of the ribs, and is smooth and hard; his spleen is very much enlarged, reaching nearly to the navel; there is pain on pressure over the gallbladder; urine is of light color, specific gravity 1.014, reaction acid, traces of albumin, mucus, hyaline, and a few fine granular casts.

Blood examination shows 2,980,000 red cells, and 30,000 white cells, plasmodia estivoautumnal type, and a large number of crescents are found. Temperature varied between 98° and 99° to December 20, when he left the hospital, his general condition improved, and blood free from plasmodia. Spleen was very much decreased in size.

On examining the nervous system more thoroughly, it could be easily demonstrated that the muscular weakness of the left arm and hand was specially marked, and the sensation of touch and pain of the third, fourth, and fifth fingers of the left hand and the outer portion of the thigh was lost. A pin could be thrust deep into the skin without the patient noticing it, whereas the adjoining portions were rather hypersensitive to touch as well as to pain. The sense of heat and cold was not disturbed. It has been mentioned before that he had a constant sensation of numbness and other abnormal sensations in these distinctly marked areas; otherwise the nervous system was found intact. The area affected in the hand corresponded to the cutaneous distribution of the ulnar nerve, and that of the thigh to the external cutaneous, though adjoining nerve fibers were involved.

The case is interesting because a leukocytosis is rare in malaria, always due to a complication, and it adds one more to the large list of nephritis due to this disease. The man had never been a drinker, had never contracted syphilis, glands were not enlarged, and there was no sign of old scars, etc., and other symptoms of chronic lues. He had never passed through any of the infectious diseases; had always led a regular life. A hypertrophy of the left ventricle could not be made out, and the superficial arteries for a man of his age were in good condition, whereas the urinary symptoms were those of an interstitial nephritis. It is most probable that the nephritis was caused by his recent attack of malaria. Another feature of the case is that he was free of fever and chills as long as he was under our observation. It is one of those cases in which the patient is constantly ailing, every organ being more or less degenerated, every function altered, the blood loaded with pigments and plasmodia, yet an equilibrium is established that allows the patient to go on, and in many instances to perform his daily work. Of special interest, however, is the peripheral neuritis. A large number of these cases has been recorded, yet they are not of daily occurrence, and always attract attention. On the other hand, neuralgias are a common feature of the disease, and we all know how difficult it is, and sometimes even impossible to differentiate neuralgia from neuritis, the one passes so gradually into the other.

If we examine the etiology we find that alcohol is a

prominent feature in both, arsenic, mercury, lead, the toxins of spoiled meats, and all the infectious diseases—typhoid, malaria, pneumonia, diphtheria, mumps, rheumatism, dysentery, and all the rest may cause either. Diabetes, gout and all other cachexias—arteriosclerosis and old age, and the severe anemias may produce neuralgia or cause neuritis; gastrointestinal disturbances, especially constipation are a common cause of neuralgia and sometimes of neuritis. Cold and excessive work are the direct cause in both, though emotion frequently produces neuralgia when any of the remote causes exist, whereas it cannot cause a neuritis. The seat of the trouble in both is in the course of a nerve and its distribution, though in neuralgias the nerve-endings are more usually affected. Neuritis is often accompanied with fever, but an absence of temperature is not rare by any means.

The symptoms are paresthesia and pain, numbness in the feet and finger-tips, pain along the affected nerves, which is increased on pressure, excessive weakness, so much so that it prevents the patient from walking for weeks and months, paresis, paralysis, and atrophy of the affected muscles as the disease progresses. The symptomatology varies according to the cause. Alcohol neuritis is especially characterized by affecting a number of muscles at the same time, and the extremities are far more frequently affected than the nerves of the trunk; that following diphtheria usually attacks the muscles of the throat. If the neuritis is due to one of the infectious diseases, we have fever, delirium, an enlarged spleen, gastrointestinal disturbances, and in some cases jaundice.

In neuralgia we have pain as in neuritis, affecting a nerve trunk or its distribution, but the character of the pain differs; it is paroxysmal remittent or intermittent, it is lancinating, cutting, and boring, and frequently relieved by deep pressure, though often aggravated by touch. The pain is produced by emotion, draught, eating, coughing, motion, etc. The attacks are often accompanied by vasomotor disturbances, local perspiration, flow of saliva and of tears. In rare instances the hair may turn gray, or may fall out in spots.

A pseudoparesis and paralysis is not infrequent, and makes the differential diagnosis in some cases difficult. Malaria is said to cause periodic attacks, though neuralgia, due to other causes, may also be periodic. The marked points of difference in these 2 affections are the continuous pain usually present in neuritis, and the paroxysmal pain and painful points along the nerve course in neuralgias. The increased pain in neuritis on pressure and the relief that follows pressure in neuralgia, anesthesia, and paresthesia are hardly ever present in neuralgia; paralysis and paresis in neuritis, and pseudoparesis and paralysis in neuralgia; atrophy in the one, though wasting may be observed in the other.

Thanks are due to Mr. deBuys, R.S., for assistance in the management of the case reported.

HALLUCINATIONS OF VISION.¹

BY

HOWARD F. HANSELL, M.D.,
of Philadelphia.

Under the euphonious title of "Mimicries of Vision," Dr. de Schweinitz has called attention in the editorial columns of 2 recent numbers of the *Medical Record* to symptoms that might be ascribed to ocular causes, but which are really the ocular expression of general disorders. My title, which might with propriety be substituted for the word mockeries or delusions refers to a different aspect of the subject—namely, the erroneous mental conception derived from diseases of the interior of the eye by which the retinal or nervous stimulus is

perverted. This is again essentially different from the hallucinations of brain disease, from the delusions of mania a potu, from dreams, or the visions of the trance state. Thus visual hallucinations may be classified under 3 varieties: (1) Those that arise from ocular disease (organic and peripheral); (2) those that arise from localized disturbance of the circulation of the brain (the so-called functional nervous diseases which may arise from peripheral or central causes), and (3) those from organic disease of the cortical centers (central). There is also a fourth variety that does not lend itself easily to classification. I refer to the exceedingly transitory imaginings, probably also due to localized cerebral congestion or anemia, not infrequently found in the subjects of uterine or ovarian disease, particularly evident at the menstrual periods. With all of these varieties the physician is intimately concerned. They are symptoms of pathologic states dependent in all instances upon local or general disease, and while they are interesting to and have been studied by psychologists, they belong preeminently to the domain of medicine.

Ocular mockeries of vision, those delusions of sight for which ocular disease is responsible are manifold and embrace mistaken conceptions of objects in the world of reality, and their transformation into other objects that exist only in the world of imagination. They owe their being to:

1. *Errors of Refraction.*—Myopes have an inaccurate impression of size, distance, color, and detail, and err in their judgments of matters concerning which their only or chief information comes through their organs of vision. So much is left to the imagination in the make-up of a landscape, a picture, a human face, that they suffer a rude awakening when made to realize by glasses the real appearance of things. The hypermetrope sees the detail, but misses the harmonious whole. The astigmatic individual sees the square an oblong, the circle an oval, and fails to perceive with equal clearness simultaneously all parts of an object. These facts are so well known that elaboration or further illustration would be a supererogation.

2. *The Ocular Muscles.*—The patient with a paralyzed ocular muscle receives 2 impressions of every object, neither of them correct, because the mental conception must be formed without the association of the binocular coordination and the physiologic double retinal image.

3. *Opacities of the Media.*—The mental impression of opacities of the cornea is that of cloudiness; of opacities of the lens, that of a fog; of opacities of the vitreous, that of smoke. Minute scattered vitreous opacities are extremely deceptive, and lead the patient to believe he sees flies, spiders, webs, that elude his grasp as he reaches to brush them aside.

4. *Disease of the Retina, Choroid, and Optic Nerve.*—Irritation of the rods and cones of the retina and the axes cylinders in the nerve and retina by the pressure of blood or inflammatory material accentuates the normal activity of the tissues and the field of vision is occupied by brilliant meteoric displays of flashes and circles of light, bright or colored rings or waves of light rapidly passing from one side to the other, or emanating from the center and spreading toward the periphery, startling and real while they last, and their disappearance followed by a feeling of intense relief. The brilliancy and frequency of the attacks depend upon the intensity and chronicity of the affection. The perversion or distortion of objects, micropsia, megalopsia, etc., is the erroneous mental conception of the imperfectly formed images on diseased patches in the retina, particularly of the foveal region. Scotomas and sectional defects in the field are usually ascribed by the patient to causes extraneous to himself until his judgment teaches him that the defects exist only for himself.

True hallucinations of vision are independent of ocular conditions, and are properly referable to mental disorders. The subject has often been written about, and

¹ Read before Section on Ophthalmology, College of Physicians, December 15, 1903.

every practitioner of experience has met many cases. A most interesting monograph has been published by the late Dr. Edward H. Clark, of Cambridge, Mass. He considers the mental delusions apparently originating in the sense of sight, but which have no connection with ocular disease, under the title of "False Vision," or "Pseudopsia," a word of his own coining. He deals with the subject from the standpoint of the physician and physiologist. For a clear, comprehensive, and systematic exposition from the standpoint of the ophthalmologist, I refer to the paper by Posey in "Transactions of the Philadelphia County Medical Society, 1895."

As an illustration of the wellknown fact that peripheral irritation may give rise to mental symptoms simulating the insanity of cerebral disease I record the following case. In the spring of 1902 I was requested by Dr. Anderson, resident physician in the Insane Department of the Philadelphia Hospital to see a patient under her care.

The patient, a woman of 25, was admitted to the hospital 2 months before. Her parents stated that she had been born blind, and consequently had received her education in a blind asylum. She had displayed evidences of average intelligence, and upon completion of her course had been placed in charge of the training of children in the school. After some years she was obliged to relinquish this position on account of violent pain in the head and delusional insanity. She became unmanageable, and was removed to the Philadelphia Hospital. I found a pale, emaciated, small woman confined to her bed and crying out during all her waking hours that her room was on fire and everything before her was enveloped in a bright red glare. This delusion was constant and never varied. The patient also appeared to be in great pain, but whether physical or mental, could not be determined. Both eyes were injected, tender to the touch, sightless, and atrophic. In order to relieve the possible ocular source of her delusion, both eyes were enucleated. The girl gradually became more quiet, until in a few days after operation, her mind regained its former clearness, and all delusions vanished. In a short time she resumed her occupation of teaching.

AN UNUSUAL FORM OF TUBERCULOUS DISEASE OF THE CHEST.¹

BY

J. N. HALL, M.D.,
of Denver, Colo.

I have seen several examples of an unusual form of tuberculous disease of the chest, not generally accurately diagnosed, and giving rise to much confusion as to prognosis as well. Although, if my explanation of the trouble be the correct one, the pathology of these cases is fairly familiar, the fact remains that the type of disease is not described in the textbooks to my knowledge, and in none of the cases mentioned, had anything like an exact diagnosis been advanced. As the first case was that of a physician, and the second that of a physician's wife, and as both had been examined many times by medical men of excellent education and wide experience, with practically the same findings at all times, I am forced to conclude that the present or some better exposition of the true condition is called for. In other words, if there be agreement as to the history and physical signs, but no exact diagnosis, the disease needs further description. I have seen other examples than the ones quoted, but wish to present a few sharply defined types, rather than numbers of cases less clear in outline, for ordinary lung tuberculosis may easily be associated with this variety of the disease.

CASE I.—A male physician, aged 62, formerly a resident of Ohio, has been in Colorado 13 years, coming here for his health. Twenty-three years ago, while much overworked, he had ill-defined distress in the chest, almost incapacitating him for work. After exertion one day he had an attack of hemoptysis. Another followed in 2 weeks, and for 3 years he never went longer than 6 weeks without one. He was distinctly relieved by the hemorrhages, and had very little cough during all this time. For the next 3 years he spat blood at irregular intervals. He then removed to Denver. In six months he considered

himself absolutely well. After several years he began to expectorate bloody sputum, and had a prolonged attack of bronchitis. Tubercle bacilli were found at this time. He gradually improved again. In June, 1901, he removed to Los Angeles, and in a few months was very much better, so that he bought property and settled down. Since that time the old symptoms have returned, and he suffers from oppression in the left chest. During the intervals of improvement he returned to his normal weight, 146 pounds. At times profuse purulent expectoration has been present, at other times, none at all. Dr. Robert Levy, of Denver, once examined him for loss of voice, but found nothing to account for the trouble in the larynx. He stated, however, that he believed the trouble to be tuberculous. It is interesting to consider whether the aphonia may not have been from pressure of enlarged glands upon the vagi, relieved later by subsidence of the inflammation, without permanent damage. I saw the patient but once, but the most careful examination failed to reveal any signs of disease in the lungs. When I mentioned this to him, he stated that all the doctors he had seen for 20 years had told him the same thing, Drs. Wm. J. Rothwell and F. E. Waxham, of Denver, included. The nails were not clubbed. His heart was slightly hypertrophied, and his aortic second sound moderately accentuated, presumably from incipient kidney disease, but I had no opportunity to examine the urine. No enlarged glands were found, and there was no abnormal dullness under the sternum.

CASE II.—Mrs. N., 40 years old, wife of a physician. Father probably died of tuberculosis. For about 12 years she has had tuberculosis, and has been examined by many physicians. During much of this time her husband has been in the medical department of the army, and has been stationed at many posts in the West, as well as in the Philippine Islands. Once in two or three years during this time she has had a feeling of oppression in the chest, relieved in a few days by the occurrence of sharp hemoptysis. This bleeding occurs two or three times, and for some months she has much cough and purulent expectoration, containing tubercle bacilli. They have never been especially numerous, but the examinations have always been positive. She loses flesh at these times, but regains it in the intervals, and now is at her full weight, 140 pounds. While living at Catalina Island, Manila, and Los Angeles she has always been better than at Fort Wingate, Denver, and other elevated stations, where she has had all her hemorrhages. I found her chest finely developed, and the resonance absolutely normal. In the lower chest, occasional crackles were to be heard, but evidently simply from disuse of the lung temporarily, since they disappeared upon deep inspiration. If any other signs of tuberculosis existed, a most careful and prolonged search failed to reveal them. There were no enlarged glands anywhere, and no dullness was present over the upper sternal region. The nails were not clubbed, and I found nothing to prevent my passing her for life insurance, so far as the physical examination went. I recommended her removal to Los Angeles, where she had done well before, and have heard that she is now again in perfect health.

Dr. C. P. Conroy has given me a most carefully kept history of a third patient, from which I have abstracted the following notes:

CASE III.—Y., male, book-keeper, aged 29. Sixteen months ago he had severe diarrhea, and was below par until 8 months ago, when he developed a cough with hemoptysis, and purulent sputum containing tubercle bacilli. At present he is considerably below his normal weight, expectorates an ounce of almost pure pus daily, and this contains tubercle bacilli in the greatest abundance. Absolutely no physical signs are present in the chest to account for all this trouble, and the further physical examination is negative. I believe this case is one similar to the first two, but in the beginning stages, and venture the prediction that it will follow a course similar to that of the others.

The striking feature of these cases is that no physical signs are to be found, such as we ordinarily expect in cases with history of cough, expectoration containing tubercle bacilli, and hemoptysis. But the cough, the blood, the pus, and the bacilli must be accounted for in some way.

It seems obvious that they come from the chest, but I cannot believe they are from the lung proper. I have seen many cases with similar history, one coming to my notice today, in which the explanation is that a small cavity exists well walled off, but capable of furnishing the sputum, bacilli, and blood at intervals for years, but the signs of its presence are entirely clear upon auscultation and percussion. I cannot believe that such a focus can escape a careful physical examination. I believe, however, that we may explain all the trouble readily if we conceive of a slow tuberculous ulcerative process in the bronchial glands. Almost the only direct reference in the textbooks that I have found is Percy Kidd's

¹ Read at the meeting of the Denver City and County Medical Society, November 8, 1903.

statement: "In some cases the continued absence of adventitious sounds may suggest the glandular origin of the lesion." But he makes no mention of the peculiar course of the disease in these cases.

I have, in a previous communication, quoted many cases, and references too numerous to repeat here, going to prove the frequency and severity of such tuberculous processes. The common history, as illustrated at the postmortem, points toward a gradual enlargement of a tuberculous bronchial gland or a group of them, eventual softening, ulceration into the bronchus, gradual emptying of the contents, suppuration within the cavity thus formed, liberation of tubercle bacilli at times in great numbers, frequently hemorrhage from ulceration into a considerable neighboring vessel, gradual retraction of the suppurative focus, with final healing, and possibly, years later, a repetition of the process in a neighboring gland or group of glands. We must note the proneness of a tuberculous process in cervical glands, for instance, to spread from one group to another, over periods of years, in an analogous manner. All this trouble may go on deep in the chest, near the bifurcation of the trachea, and not within the radius of successful detection by percussion or auscultation. Occasionally the cutting off temporarily of the respiratory murmur in the area supplied by one bronchus gives us a hint of the presence of such a glandular enlargement pressing upon that bronchus, but I must dissent forcibly from the views of certain authors as to the possibility of frequently detecting the presence of these glands during life. The trouble certainly goes on within them in most cases, not only undetected, but unsuspected.

The periods of active symptoms in these cases of course correspond to those of the destruction of the enlarged glands, and the periods of quiescence to the intervals between such breaking down processes. The lungs show no signs, or at most only temporary and uncertain ones, because the disease seems prone to remain, in many cases, a glandular tuberculosis throughout its course.

The tendency to improvement at seashore resorts so noticeable in at least one of these cases is in line with the long recognized fact that glandular tuberculosis is frequently improved by sea air. The failure of cure by altitude treatment is accounted for by the fact that it is not a pulmonic disease, and lung tuberculosis is the one process above all others most benefited by such treatment.

The good condition of the patients between the periods of activity is in line with the vigor of the individual with tuberculous cervical glands when these are quiescent. The severity of the hemorrhages in the cases is accounted for by the fact that they do not arise, like most pulmonary bleeding, from capillary regions, but from ulceration into a considerable artery or vein. The curious finding of bacilli in abundance at times, and their decrease, or even absence at others is just what we might expect from a study of the pathology of the trouble, although we recognize the fact that in many cases the tubercle bacillus is not to be demonstrated, excepting by inoculation, in tuberculous bronchial glands.

Finally, if there be any other explanation covering all the features of these curious cases I shall be glad to listen to it. Fortunately my own patients have lived so long that anatomic demonstration has been lacking.

Wholesome Advice from Lay Source.—The Chief Burgess of West Chester has issued a proclamation of New Year's greeting to his people, and at the same time, after the manner of Moses, has given them 10 wholesome rules to follow. They are as follows: Don't get mad; walk a mile a day; abstain from pork; wash and be clean; eat moderately of good food, but eat all the apples you can; speak to everybody; stand up straight and look people in the eyes; respect age; stay at home; sleep with your windows open to the 4 winds of heaven.

OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA IN YOUNG CHILDREN.

BY

PEARCE KINTZING, B.Sc., M.D.,
of Baltimore, Md.

Professor of Surgery, Woman's Medical College, Baltimore; Surgeon to the Good Samaritan Hospital, the Hospital of the Woman's Medical College.

Although, as pointed out by Agnew many years ago, a certain proportion of children with inguinal hernia recover by persistently wearing a properly fitting truss, still this is the smaller proportion, and the number is less than those who recover from umbilical hernia; while the difficulties experienced in compelling many children to wear a truss persistently are almost insurmountable. In many instances the truss is worn for the greater part of the time, over the unreduced hernia, thereby increasing and perpetuating the trouble.

As has been intimated, a certain class of these cases persists, in spite of properly fitting and continuously worn trusses, and the disease is even aggravated by the mechanical support, which seems by its pressure to increase very materially the patulousness of the canal. In these cases there is not only present the anatomic defect as to the inguinal canal, of which I will speak later, but muscular insufficiency as well. Here, sooner or later, the mass, which slowly increases in volume until it reaches the scrotum, becomes irreducible, owing to the contents of the sac, generally the omental portion, becoming adherent to its walls, by reason of the inflammation excited by the pressure of the misdirected truss and the impeded circulation from the same cause. An examination of the anatomic factors of these hernias will reveal that they are of that variety of congenital hernia in which the prolongation of the peritoneum over the spermatic cord, the funicular process, has failed to contract around the cord and thereby to shut off the abdominal cavity; hence, even before the descent of the bowel, the peritoneal cavity is one with the interscrotal space. In brief, the tunica vaginalis testis is continuous with the peritoneum.

While hernias of this class offer least hope of cure by means of the truss, yet they are the most hopeful from the standpoint of operation, although they present a certain difficulty to which little or no reference is made by systematic writers on this subject, and one object of this paper is to call attention to this fact.

None of the operations yet devised for the radical cure of hernia has succeeded in preventing a return of the defect in a certain proportion of the cases, either in adults or children, yet it seems to me that young children offer the most favorable field for total and permanent success by operative means. They bear both operation and restraint well, and, since the radical operation is accompanied by but little shock, reaction and recuperation is very rapid, much more so than in adults.

While all of the factors concerned in the production of hernia are not known, yet it is safe to assume that the principal agent is the anatomic defect before emphasized, that is, the failure of the peritoneum to close tightly around the cord. The gut entering the funnel thus left for it, acts as a wedge, and acts unceasingly, aided by gravity, stooping, coughing and straining. The result is inevitable. In children then, much more than in adults, is the principal mechanical difficulty overcome by proper closure of the peritoneal infundibulum. The conditions of growth and muscular development being normal, nature will do the rest. However the closure of the intercolumnar space is by no means to be neglected, although I do not regard this closure as the prime requisite in producing a cure in children, but rather the perfect obliteration of the peritoneal opening. The more nearly we can come to obliterating every vestige of this space, the more certain we are to accomplish our object, and heretofore sufficient emphasis has not

been laid upon this fact. The intermuscular canal is normal, the infundibular opening is not.

As pointed out by Deaver, to obliterate or to displace even the dimple in the membrane, which normally exists behind the internal ring, is of the highest importance. That faulty muscular development is not of itself sufficient to produce the lesion, may be inferred from the fact that it will be frequently noticed that after the reduction of even a large unilateral hernia in a child, no difference can be detected in the relative size of the 2 canals, *i. e.*, the intercolumnar opening, yet the descent occurs only on the one side, the side on which the peritoneum is patulous. More often this defect exists on the right side than on the left. Likewise how often do we find on examination of elderly males, canals into which the finger may be introduced almost to its full length, yet these persons have never been the subjects of hernia.

How long shall we endeavor to effect a cure by mechanical appliances? The axiom that there are no hard and fast rules in medicine or surgery, applies here. Some cases are evidently hopeless from the outset. Is it conformable with surgical conscience to delay in these cases? From my standpoint, the earlier such patients are operated on, the greater the chance of success. This class includes all cases in which the reduction can not be maintained for the greater part of the time, since it follows that each recurrence not only reproduces, but exaggerates the original conditions in their entirety. Under these circumstances, how are we to effect a cure by supports? The second class should include those cases in which the reduction may be maintained more or less satisfactorily, but which show no improvement after a year or 18 months' trial.

A sad case which came under observation at my clinic, was that of a child of less than 4 months, with a large protrusion which had become incarcerated, and so remained for over 24 hours, until all the ordinary symptoms of acute obstruction had developed. Under anesthesia the bowel was replaced, but 2 weeks later the child was brought back with a return of the difficulty. Taxis failed to relieve the strangulation, and the necessity of an operation was explained, but the mother absolutely refused consent, and the child died a short time afterward.

The youngest child upon whom I have operated, in whom no strangulation existed, was aged 1½ years. This child had a large scrotal hernia which had become irreducible. In this case the condition to which I have already made reference was present, that is, the sac of the hernia and the tunica vaginalis testis were continuous. The various elements which go to form the cord were spread out upon the sac, as though forming an integral part of it. It is plain that in such a state of affairs the sac can not be ligated and amputated, as is usually directed. It is necessary to first free the sac up to and well within the internal abdominal ring; then to slit it up to within a short distance of this point; to free and return its contents to the abdominal cavity. Next to dissect out carefully the vas deferens and its vessels—by no means an easy task, ligating supernumerary veins; close off the sac at as high a point as possible, so that when liberated the sac will retract well within the abdominal cavity, leaving one of the ligation threads long, in order that the stump may be transplanted if necessary. This transplantation is best accomplished by passing a long curved needle downward and inward, through the transversalis fascia toward the conjoined tendon and drawing the stump behind and against this structure.

My custom has been to draw up the downward continuation of the sac, until the upper orifice of the scrotum is reached, then to cut off at this point the cuff-shaped expansion, which has formed the hernial sac, leaving a tongue-shaped process, to which is attached the cord as before described. In my experience the remain-

ing portion, which drops back into the scrotum, even though much thickened, has taken care of itself without causing any disturbance. Omentum which has been contained in the sac is, of course, freed and returned, or removed as may be deemed necessary. The suturing is done in the usual manner. The dressing is retained by a plaster-of-paris spica around the thigh and the crests of the ilia, which is continued for about 4 weeks. This form of dressing absolutely prevents movement of the parts, and yet allows the child to be kept almost continually in the fresh air, a desideratum not to be overlooked.

SPECIAL ARTICLES

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Proceedings Reported by the Secretary.

WILLIAM J. GIES, M.S., Ph.D.,
of New York.

The fourth regular meeting of the Society for Experimental Biology and Medicine was held in the demonstration room of the Department of Physiology, of Columbia University, at the College of Physicians and Surgeons, on Wednesday evening, December 16. Dr. S. J. Meltzer presided.

Reports of original investigations were offered as follows:¹
"The changes in the viscosity of the blood produced by various experimental procedures, with demonstrations": R. BURTON-OPITZ.

Dr. Burton-Opitz described and demonstrated the apparatus used in determining the viscosity of the blood. This demonstration was followed by a discussion of the changes in the molecular friction of the blood after intravenous injections of distilled water, saline, dextrose, and alcoholic solutions. The effect of alcohol, when introduced into the stomach and small intestine, was also noted. Next were considered the changes following subcutaneous administration of curare and the differences in the viscosity of arterial and venous blood. K, the coefficient expressing the viscosity, was determined before and after each experimental procedure, 2 or 3 determinations being made in each case.

It was found that, if distilled water, in quantities of from 5 cc. to 50 cc., is slowly allowed to flow into the facial vein, the viscosity of the blood is increased, but the increase is not considerable. The following experiment may serve as a sample: The normal coefficient K, in a dog weighing 19.2 kilos, was 802.6, or 5.8 times greater than K for distilled water at 37° C. After the injection of 10 cc. distilled water the coefficient showed the value 786.0, or 6.0 times greater than distilled water at 37° C. Normal saline solutions produce the reverse effect, *i. e.*, the blood becomes less viscous. In one case after injecting 10 cc. of 0.7% NaCl solution, the viscosity of the blood fell from 5.9 to 5.6 times that of distilled water at 37° C. Concentrated solutions of dextrose (5 cc.) injected into the facial vein bring about an increase in the viscosity of the blood, which is more pronounced than that produced by distilled water. About a half hour after the injection the coefficient K shows again its normal value.

If from 3 cc. to 5 cc. of 10% or 25% solutions of alcohol in water are allowed to flow into the facial vein, the molecular friction of the blood becomes greater. The same result can be obtained by introducing the alcohol directly into the stomach or duodenum; 30 cc. of a 25% solution were injected into the stomach. The viscosity determined 20 minutes later showed the value 608.09, as against 664.17, the normal coefficient. Thus, instead of being only 7.0 times greater than that of distilled water at 37° C., it changed after the injection to 7.7 times greater. An equally decisive change occurred after injecting 40 cc. of a 25% solution into the duodenum. A marked increase in viscosity also follows subcutaneous administration of

¹The abstracts here given have been prepared by the authors themselves. The secretary has made only a few abbreviations and minor changes.

curare; however, this result is not evident until the respiratory muscles become paralyzed.

Venous blood is slightly more viscous than arterial, but the difference is often very insignificant.

In all these determinations a direct parallelism exists between the viscosity values and the specific gravity. When the viscosity increases, the specific gravity increases also, and *vice versa*. Not a single exception to this rule could be found.

The viscosity was also determined in a dog having very large thyroid bodies. The right gland weighed 57 gm., the left 52 gm. The viscosity-coefficient, obtained by 8 determinations, showed the value 1233.17 (specific gravity, 1.05028), which means that the blood of this animal was only 3.8 times more viscous than distilled water at 37° C. The lowest previous value obtained by Dr. Burton-Opitz occurred in a dog after 3 days of hunger. K equalled in this case 1110.3 (4.2 times more viscous).

In general, it may be said that the less the viscosity the longer the period required for extravascular coagulation. This was especially well shown in the case just mentioned. Clotting set in after about 15 minutes.

"Survival of an animal after removal of both suprarenal capsules, due to a previous grafting of the organ into the kidney.": S. J. MELTZER (for F. C. Busch and Charles van Bergen, of the Department of Physiology at the University of Buffalo).

Dr. Meltzer stated that in several instances survival of a part of suprarenal grafts was obtained after transplantation into the kidney of the same animal.

In one experiment the animal (a rabbit) survived, after apparently all other suprarenal tissue, aside from that which was grafted into the kidney, had been removed. In this case, after total removal of the left suprarenal, a part of the gland, including medulla and cortex, was introduced through an incision into the cortex of the left kidney. Eighty-six days later the remaining right suprarenal was removed *in toto*. The animal survived the operation and was apparently normal for 21 days, at the end of which time it was killed in order to examine the graft. This was found, upon histologic examination, to have been in part replaced by connective tissue. The surviving cells apparently belong to the medullary portion of the suprarenal. The cortex had been replaced by connective tissue. Blood supply was good.

Slides showing the successful grafts were exhibited under the microscope. In this connection, also, Dr. Meltzer showed, under the microscope, a section of Zuckerkandl's organ, the chromophilic bodies of which are similar in nature to the chromophilic granules of the medullary portion of the suprarenal capsule.

"On the absence of a cane sugar inverting enzyme in the stomach": GRAHAM LUSK.

It was shown by Professor Lusk that free hydrochloric acid and not an enzyme caused the inversion of cane sugar in the stomach.

"A new head holder for rabbits, with demonstration": FREDERIC S. LEE.

The following reviews were made:

"The action of potassium cyanid upon the unfertilized egg": HOLMES C. JACKSON.

Loeb and Lewis were the first to note the fact that unfertilized eggs (of the sea-urchin), when placed in $\frac{n}{1000}$ KCN solution, retain their capability of fertilization much longer than when suspended in normal sea water. This was ascribed to the action of the KCN in inhibiting intracellular autolytic processes which lead normally to maturation and finally death. The bactericidal action of KCN was excluded, as the result of experiments in which eggs apparently died as rapidly in sterile as in putrid sea water.

Gorham and Tower's experiments in the same connection indicated, on the other hand, that the effect of KCN was entirely bactericidal. The sterile eggs retained their capacity for fertilization longer under absolutely sterile conditions than when placed in $\frac{n}{1000}$ KCN.

As the question now stands there exist two almost identical series of sterilization experiments by 2 pairs of investigators, with results diametrically opposed to each other. Critically considered, the more carefully conducted experiments seem to be those by Gorham and Tower; and in the lack of further evidence in favor of an intracellular action of KCN in this connection, we must conclude that the destruction of the bacteria by the KCN removes the condition which causes the death of the cell and in the absence of which the eggs retain their potential power for growth after fertilization.

Results of recent investigations in proteid chemistry: P. A. LEVENE.

Recent work on the chemistry of the proteid molecule has furnished explanation of many biologic phenomena. Thus in certain pathologic conditions there appears in the urine a sulfur and nitrogen containing substance, cystin. The source of the substance in the organism had been unknown until, through the efforts of Mörner and Embden and others, its radical was demonstrated to be a normal constituent of the proteid molecule.

The chromatin of a developed cell differs from that of an unfertilized egg by the presence in it of radicals of purin bases. It is probable that these bases are derived from the histidin radical, which is also a normal constituent of proteids.

Hemoglobin is known to be absent from the unfertilized egg, and it appears only in course of development of the embryo. It was shown recently that the nonproteid part of hemoglobin is a pyrrol derivative, and it is probable that a pyrrol radical is present in the proteid molecule. Chlorophyll is also a pyrrol derivative, a fact further establishing its close relationship to hemoglobin.

The work of Emil Fischer points to the way in which the various component radicals may combine in order to form the proteid molecule, and makes probable the eventual synthesis of true proteid material.

NEW MEMBERS.—The gentlemen named below were elected to membership: A. C. Abbott, Isaac Adler, B. H. Buxton, J. McK. Cattell, H. L. Cushing, E. K. Dunham, Simon Flexner, Reid Hunt, Hugo Münsterberg, J. A. Murlin, Horst Oertel, E. L. Opie, Theobald Smith, A. B. Wadsworth, R. S. Woodworth, Naohidé Yatsu.

Vermin Destroyed.—During 1902 185,982 rats were killed at the London docks, and the total destruction for 1903 amounts to nearly 70,000.

Oleomargarin in Dining Cars.—According to newspaper reports analysis made of the food served in the dining cars of the various railroads operating in Pennsylvania has determined Dr. B. F. Warren, State Dairy and Food Commissioner, to bring suit against a railroad running through the northern part of this State. What was served as butter on a dining car in October is said to have been shown by analysis to be oleomargarin. Butter procured on other roads proved to be pure. Analyses are now being made of liquors purchased on buffet cars, and prosecutions may follow the report of the chemist. As railroads are under Federal jurisdiction, an effort is being made to secure the cooperation of the Federal authorities in bringing suit.

The Contagion of Crime Spread by the Press and by Literature.—D. Román Pacheco (*La Escuela de Medicina*, October 31, 1903) addressed the Fourteenth International Congress of Medicine, held at Madrid, and pointed to the necessity for restricting the sale of printed matter which publishes crimes of an emotional nature, and insisted that newspapers and journals of wide circulation do great harm in giving as news, matter calculated to inflame criminal natures and instincts. There is a curious liking on the part of many to read, hear of, or see represented, criminal affairs under the guise of heroism. This must be atavistic, and is suggestive of premonal stages in the human development. Authors and journalists should enlarge the range of criminal matters on which it is forbidden to write. Youth should be encouraged in the higher instincts—led forward, not backward. Criminal slang is taught them by journals. They learn the language and acquire the mode of thought. A certain journal published the fact of some one killing himself after telephoning full directions as to the disposal of his body by some undertaker, and its burial. In 2 months the crime is duplicated. When crime is taken from the side of the law and its correction given over to the hands of the medical faculties, better success will be gained in controlling it, and in regenerating the criminal. Meanwhile the necessity of restraint of publication of inflammatory topics should be considered.

1.—See *American Medicine*, Vol. V, No. 22, p. 849.2, 3.—See *American Medicine*, Vol. V, No. 22, p. 863.

4.—**Professional Responsibilities.**—A. E. Baldwin emphasizes the far-reaching effect of dental work, or the lack of it. Responsibilities begin in advising care of the temporary teeth as even more important than those of adults. When mastication in a child is painful, bolting of the food with consequent digestive and nutritional disturbances follows. With loss of a tooth at this time, the tooth behind moves forward, preventing the proper eruption and corresponding expansion of the arch with irregularity. The first permanent molar is the most important to preserve. Its loss produces deformities of the lower part of the face. The writer also emphasizes the importance of treating small cavities, thus preventing them from getting bad. While much more work must be done at the time, a great amount is saved subsequently. Bridge-work or crowns may, by improper adjustment, cause the ills they were intended to rectify. Great care must be exercised to make the articulation natural, that the force of mastication may be on the lines of natural resistance. [H.M.]

5.—**Tolerance of the Tissues to Foreign Bodies.**—M. H. Fletcher presents cuts of elephants' tusks, one containing an encapsulated lead bullet, the other an iron bullet rolling around in what seems to have been a pus cavity. The protrusion of a broken breach from the apex of the root of a pulpless tooth seems invariably to cause an abscess, whereas the protrusion of a gutta-percha point causes no trouble. Wax and paraffin are unirritating to granular surfaces. Caseous pus and trichinas may become encapsulated. Needles may wander through the flesh without pain or apparent damage. Certain substances are *per se* noxious. Those that are most innocuous are impervious to moisture and more or less yielding in character. Hard, smooth substances may be tolerated, but if roughened by chemic action they produce trouble. Cloth and wood seem especially noxious. Intrinsic foreign bodies includes sequestra, pulpless teeth, calcareous or phosphatic deposits. These deposits about the neck of the teeth are always irritating, and are so situated that bacteria have free access to the irritated tissues, and pyorrhea alveolaris with autointoxication results. In man owing to the anatomic conformation of the pulp the blood and nerve supply is limited to the minimum, so that in case of injury there is no collateral circulation or nerve supply for rapid repair as in other tissues and in the teeth of the lower animals. A pulp may be capped with any innocuous substance, providing it does not press on it. Irritation may cause the formation of nodules of dentine which act as foreign bodies in turn, the attempt at repair defeating its own object. So long as tartar is present irritation is continuous, sequestra are formed, which are a second source of irritation. Healing occurs by removal of the deposits or sequestra, or by loss of the tooth. The latter invariably results in recovery. [H.M.]

6.—See *American Medicine*, Vol. V, No. 22, p. 900.

7.—**Urethrotomy by the Combined use of an Anterior and Posterior Sound.**—G. W. Penn discusses current methods of treating impervious urethral stricture when it is impossible to locate the proximal lumen. He believes Cock's method not justifiable when there are others less tedious and difficult; and this is also true of cystotomy for posterior catheterism when

done simply as a guide. The latter is used by most surgeons when other means are impossible. He quotes from many well-known writers. He himself has resorted to prevesical puncture, the procedure having been accidentally suggested to him in a case requiring immediate tapping. The canula bent to a curvature slightly less than that of a urethral sound was used as a passage for a post-urethral guide. Any discrepancy between the urethral curvature and that of the canula can be overcome by the facility with which the position of the canula itself can be shifted owing to the great degree of invagination above the pubis, the mobility of the abdominal wall permits. The bladder should be filled with salt solution and the penis grasped in order that there may be as few obstructing folds as possible. Dilation of the urethra posterior to the stricture, usual in these cases, increases the ease of the procedure. The opening having been made in the bladder while distended, is smaller even than the instrument itself, hence a more complete closure follows contraction with less liability to leakage. Dorsal decubitus should be maintained for 48 hours, thus favoring drainage through the perineal wound or the natural passage, as the case may be. [H.M.]

2. On Some Questions Relative to Extrauterine Pregnancy, with Especial Reference to Tubal Abortion. MALCOLM STORER.
3. Typhoid Fever in Children. ADOLPH BAGINSKY. (Concluded.)
4. The Finzen Light Cure. H. JOHN STEWART.

1.—**Obstetric Nursing.**—A. Worcester emphasizes the advantage to the obstetrician as well as to the patient of having a well qualified obstetric nurse. During the first stage of labor no physician can do so well as a trained nurse, the service needed by the patient; he is only in the way, and such employment of his time is unprofitable. Obstetric nurses should be expected to exercise precautionary surveillance during the pregnancy, to manage the first stage of labor, to recognize any abnormal occurrence, to be able to conduct a normal labor, to apply appropriate preliminary treatment in emergencies, and in confinement to care for both mother and baby intelligently. The ideal education of the obstetric nurse includes still more. She must be taught how to fit in most helpfully in homes where the mother is under temporary eclipse; to utilize all sorts of make-shift material; to save unnecessary expense; and to make the family, and even the servants her friends. These lessons cannot be taught in a hospital ward. The schools of nursing must provide courses of instruction in obstetrics, and clinical practice under capable teachers where the education of the nurse is the matter of first and not of second importance, as it is in a maternity hospital, where the first consideration is the hospital resident. After class work and preliminary drill in the regular training school, opportunities for clinical practice can be arranged for in connection with the visiting nurse societies, who would gladly undertake more midwifery work. While under the necessity of employing graduate nurses for this purpose, it is not possible to supply the demand. But with student nurse service available, many of these visiting associations could well afford to employ a superintendent nurse competent to teach obstetric nursing. This would meet the needs of the very poor women, and of those who can pay only a very small fee for nursing service. [W.K.]

2.—**Extrauterine Pregnancy.**—M. Storer comments upon the frequent absence in tubal abortion of the classic symptoms of ectopic gestation, such as irregular flowing after a period of amenorrhea, sudden and severe colicky pains, the presence of an ill-defined tumor distinct from the uterus, and the escape of decidual tissue. Upon the last mentioned symptom he places no reliance. Grave anemia has been the exception in his experience. Tubal abortions are especially difficult of diagnosis, and yet they are more frequent than cases in which there is rupture; they formed 56% of his cases; and contrary to the teaching that ectopic gestation is much more likely to occur in multiparas, 41% of his cases were in primiparas. The symptoms which seem to the writer of most importance in tubal abortion are pain and anomalous escape of blood from the

uterus. As to treatment, he advises operation as soon as possible after rupture; and with a diagnosis of probable unruptured tubal pregnancy, a reasonable probability indicates immediate operation. Given tubal abortion some time before the patient is seen, nature will generally take care of it with an average convalescence of 8 months, while with operating and clearing out the pelvis, the mortality is no greater and the convalescence averages 8 weeks. Storer employs laparotomy rather than vaginal incision. [W.K.]

3.—Typhoid in Children.—A. Baginsky thinks it probable typhoid is often present in sucklings, the diagnosis being feverish dyspepsia. Boys are more susceptible than girls. Typhoid is more or less transmissible from person to person, and children are careless about soiling their persons. Degenerative and necrotic changes are more prominent in the intestines of children than adults. In some cases considerable meningeal effusion occurs, but real meningitis is rare. Most cases begin with indefinite symptoms. In the very young, fever may begin suddenly and rise rapidly. From the first to the tenth year the febrile period steadily increases in duration. Pulse frequently corresponds pretty closely to temperature elevation, 100, 120, 140. There may be apathy, screaming delirium, or the deepest stupor. The respiratory organs are always affected. There is usually some leukocytosis, 1 leukocyte to 650-1,200 erythrocytes. An unusually protracted angina with very high fever may be the only early symptom of typhoid. With high fever, albuminuria may be present for a week or two. Children are more predisposed than adults to relapses. On the part of the heart, adynamic conditions are less to be feared. As a rule complicating noma is fatal. Bloody diarrhea is seldom observed. Prognosis, as a rule, is favorable, but depends materially on treatment and the period at which it is begun. Errors in diet and insufficient nourishment often affect the outcome badly. Rapid, repeated, and long-continued cooling of the skin is dangerous to children, overtiring the respiratory centers, perhaps affecting the motor center. Heart paralysis may result from insufficient nourishment. The slowly cooled bath holds the fever down longer than the cold bath. Quinin is the best antipyretic. Among foods that may be given are bouillon, wine, yolk of egg with water and wine, milk, cornstarch, peptone preparations, plasmon and somatose. The intervals of feeding should be every $\frac{1}{2}$ to $\frac{1}{4}$ hour. [H.M.]

4.—Finsen Light Cure.—H. J. Stewart has visited the Salford Skin Hospital in Manchester, England, the London General Hospital, the Light Institute, at Copenhagen, and found in all of these the application of the Finsen light treatment yielding splendid results. The Finsen light has a candle power of 20,000 or 20 times stronger than the ordinary street lamp; its great advantage is in the vast number of violet rays produced. Finsen states that in lupus vulgaris 97% of cures are effected, even cases in which the whole face is involved are usually cured. In 800 patients treated, with the ages ranging from 75 to 4 years, the average duration of the disease was 11 years and the resulting cures was the average given above. This treatment has the advantage over the Röntgen rays that there is no danger of burning and consequent sloughing. With the Finsen light we are dealing with a known quantity, while with the Röntgen ray it is an unknown quantity. The former causes no pain, a red blister appears where the light is applied and in 5 or 6 days the scab falls off and the ulcer is healed beneath, the skin being free from cicatrix, and eventually free of redness. During the period of 6 years the Finsen Medical Light Institute, at Copenhagen, has grown from a small shed where only 1 patient was treated at a time to a magnificent institution in which are treated 300 people daily. 1.—Etiology, Prevention, and Management of Rheumatism in Childhood.—J. E. Winters states that rheumatism is caused by the nonneutralized acid products of proteid metabolism, and is cured by basic constituents of food. In rheumatism the perspiration, saliva, urine, and feces become acid. The alkalies of the blood are first drawn upon for neutralization. This causes disintegration of red cells. Sodium and potassium are the chief alkalies of the blood. Sodium transports carbonic acid to the lungs. Menacing symptoms in rheumatism are due to withdrawal of sodium, liberation of carbonic acid, and arrest of detoxicating oxidative processes. In chronic states the alkalies of bone tissue are attacked. Foods rich in basic constituents and vegetable acids, organically combined with vegetable proteid, with a minimum of animal proteid (yielding uric acid), and proper oxidation and elimination, cure and prevent rheumatism. Drugs may render the urine alkaline without influencing tissue fluids. Potassium and sodium compounds must be in organic combination to reach these. Cereals, potatoes cooked in their skins, and bread are rich in potassium. Salts of vegetable and fruit acids form alkalicarbonates. Masked expressions typify the rheumatism of childhood, and are the basis of nearly every case of heart disease. Rapid muscle growth in childhood with consequent acid products necessitates a large amount of vegetable proteid. With overplus of acid products the susceptible mitral leaflets feel the irritation first. Calomel followed by rhubarb and soda should be given so long as the tongue is furred. Soda should be in 20-grain doses before meals. Milk should be the sole food. When symptoms have subsided a strained cereal may be added. Animal food when allowed should be in the form of meats, not broths or beef juice, as these overstimulate metabolism. Vegetable soups are appetizing. [H.M.]

2.—Management of Fracture Involving the Joints.—Virgil P. Gibney holds that with fracture and separation of the epicondyle and condyle at the elbow-joint, to dress the forearm in full extension makes the olecranon a splint for the condyles, and prevents callus or other deposits in the olecranon fossi, thus minimizing the danger of full extension as an end result. From experience he is convinced that after such fractures full extension is harder to secure later in the management of the case than is flexion. After union is sufficiently firm, say from 10 days to 2 weeks, the extended position can be changed to that of flexion, as in supposed fractures of the neck of the femur. The employment of the Röntgen rays has enabled him, of late years, to completely differentiate bending of the neck of the femur from that of fracture; a condition which before the introduction of the rays always lent a certain amount of doubt to the diagnosis. In correcting hip deformities in adults by osteotomy, he invariably employs a plaster spica bandage, as he does in many other cases, and he is at a loss to understand why plaster bandages are not more popular with surgeons in general, unless it be that they fail to understand their proper application. [A.B.C.]

3.—See *American Medicine*, Vol. VI, No. 17, p. 656.

4.—Congenital Orbital Endothelioma in an Infant.—Mortimer Frank reports that a male infant, 8 weeks old, was brought to him with a swelling on the inner aspect of the left eyeball, producing a slight protrusion of that organ. It was situated between the internal angular process and the supra-orbital notch of the frontal bone, against the inner wall of the orbit, and was about the size and shape of a large peanut. Under chloroform anesthesia, the tumor, though adherent to the sclera, was separated by dissection and removed, leaving the eyeball in the normal situation. The child made complete recovery, the only evidence of an operation having been performed is a slight convergence which still persists. A histologic examination of the tumor led to a diagnosis of congenital alveolar sarcoma of endothelial origin. The writer, in a search of the literature, has been unable to find a similar case reported. [A.B.C.]

5.—Hyoscin Hydrobromate before Ether Anesthetization.—E. A. Robertson cites morphin, atropin, chloral, and

other drugs, which have been used in conjunction with or preceding the administration of ether, for beneficial result to the patient, fancied or real. In this connection he has practised, with entire satisfaction to himself, the administration of hyoscin hydrobromate. In man this drug causes: (1) Dryness of the mouth and respiratory mucous membranes; (2) flushing of the face; (3) great drowsiness, deepening into sleep, and sometimes semidelirious mutterings and dizziness; (4) diminished frequency of respiration; (5) diminished frequency of pulse-rate; (6) as a rule, dilation of the pupils; (7) depression of the motor nervous mechanism. He has employed the drug before operation in 57 instances. In from 3 to 10 minutes the mouth never failed to become dry, and thirst was almost always present. At the same time the pupils began to dilate, and continued in that condition until the ether was administered, though they responded to light reflex, and accommodation was not lost. Within 5 minutes, as a rule, the patient began to feel drowsy. The face was normal in color in most cases, but in a few was flushed. There were no symptoms of excitement or delirium, without dizziness or vertigo. The pulse, except in the case of one suffering from great weakness, was slow, full, and regular, and the respirations were deep, quiet, and normal. No dangerous symptoms arose at any time which could be fairly attributed to the use of the hyoscin. Indeed, the phenomena of anesthesia were slight and the course uneventful. The results in detail were as follows: Fifty-seven operations; 24 abdominal, 10 abdominal and plastic combined, 9 plastic, 2 vaginal hysterectomies, 1 cauterization of the vagina and cervix for cancer, 1 growth in bladder, 2 applications of strong nitrate of silver solution, 8 curetments. In all cases the Clover inhaler was used. The amount of the drug administered was $\frac{1}{100}$ of a grain. Vomiting occurred after the operation in about 50% of the cases. Stress is placed upon the benefit derived from hyoscin in stopping the secretion of mucus in the air passages during the action of the anesthetic. [A.B.C.]

6.—The Early Diagnosis of Pulmonary Tuberculosis.—F. S. Clarke gives the following as important in making an early diagnosis of pulmonary tuberculosis: An increased pulse-rate, gradual loss of weight and strength without obvious cause, an evening rise of temperature, digestive disturbances, numerous tubercle bacilli in the sputum, vesicubronchial breathing, small crepitant rales at the end of inspiration, the necessity of repeated physical examinations in order that we may reach definite conclusions. [H.M.]

7.—Simple Method of Examining the Stools for Gallstones and other Solid Bodies.—Howard Lilienthal says: "Take a loop of telegraph wire a few inches greater in diameter than the entire top of the closet seat, and fasten to this a bag of at least 2 thicknesses of dressing gauze or mosquito netting. The bag may be sewn to the wire or simply held by safety pins, but it should be made very full, so that when the hoop is in place the wire shall be well below the level of the seat and out of the way, while the bag shall hang down into the water at the bottom of the bowl. If the patient is not confined to bed he defecates into the closet, and then simply opens the water valve often enough to wash away all soluble matter, while solid bodies will be left in the bag. If the patient is confined to bed, the stool must be carried to the closet. In rural districts where there may be no plumbing the same procedure may be followed except that the water must be carried to the privy and poured through by hand. The principal advantage of this method, especially in city practice, is that the patient himself may be trusted to make an absolutely accurate examination. He has been able to confirm a diagnosis of cholelithiasis from tiny faceted stones considerably smaller than a mustard seed, which were discovered in the stools by the patient. [A.B.C.]

5. A Bacterial Treatment of Tuberculosis, with Reports of Cases. STEPHEN J. MAHER.
6. The Surgery of the Day. C. B. KELSEY.
7. The Ocular Complications of Mumps. J. H. WOODWARD.

1.—Surgical Treatment of Gallstones.—B. F. Curtis urges operation while the stones still remain in the gallbladder or cystic duct, and before grave infection has developed. The serious accidents of infection are thus avoided and any inflammatory condition which may exist can be improved or cured just as drainage cures urinary cystitis. The stone is removed before it enters the common duct, thereby preventing all the dangerous consequences likely to follow the presence of a stone in that passage, and further attacks of cystitis and colic are prevented. Further calculus formation is prevented or impeded, for the stones are formed in infected gallbladders, and the latter may be removed by operation or rendered so healthy by drainage that no more calculi will form. He calls attention to the fact that latent cases are by no means free from danger. The possibility of secondary pancreatitis must be kept in mind, and also that of carcinoma of the gallbladder, which he says is more common than has been supposed. Without reference to more important results, he says it is the general feeling of those with experience in the surgery of cholelithiasis, that in the latent cases, while the patients do not present symptoms pointing directly to the biliary system, they are afflicted with various dyspeptic complaints, and that the latter can be relieved or permanently cured by operation. [C.A.O.]

2.—Surgery of Stomach Diseases.—Albert Vanderveer reviews this subject, and in conclusion says: 1. That gastroenterostomy can be applied to all kinds and conditions of stenosis of the pyloric end of the stomach. 2. That it is a preferable operation to that of resection of the stomach in many cases, the immediate mortality being less and the possibility of the extension of life being quite as great, with as much comfort. 3. Next to gastroenterostomy he believes gastrectomy to be the most reasonable and satisfactory operation, yet this operation will necessarily be limited to but few cases. In doing it, great attention should be paid to removal of the lymphatic glands, as in this rests much of the permanent success of the operation and nonreturn of the malignant growth. [C.A.O.]

3.—Hysterectomy for Infectious Disease.—H. C. Deaver first outlines the early treatment of infectious disease of the uterus and uterine appendages. In cases in which the infection has passed into the tube, forming a pyosalpinx or tuboovarian abscess, he always operates through the abdominal route, tying off the ovarian vessels as close to the pelvic wall as possible, and rapidly excising the tube and ovary with scissors, following the incision right into the horns of the uterus, and closing the resulting wound with a continuous suture. He then drains with gauze, being careful to place the gauze along the line of suture. In cases in which the infection manifests itself as a phlebitis of the uterine sinuses and veins of the broad ligament, and is associated with small and multiple abscesses of the uterine walls, as well as with acute peritonitis, the author believes that an early operation is indicated. When infections of the uterus occur from gonorrhea and dermoid cysts, and from interligamentary and ovarian cysts, he performs a supravaginal hysterectomy. Supravaginal hysterectomy in badly infectious cases with dense adhesions he considers the ideal operation, for it thoroughly removes all the diseased condition and we can leave the floor of the pelvis with a serous covering by neatly stitching the opposed serous surfaces together. [C.A.O.]

4.—Cardiac Toxemia of Pneumonia.—H. L. Elsner treats the cardiac insufficiency resulting from pneumococcus toxemia by administering every 15 minutes 1 cc. (15 drops) each of the compound spirit of ether, aromatic spirit of ammonia, the compound spirit of lavender, and the tincture of valerian. This is kept up day and night until the pulse shows improved tone, and the heart action is decidedly better. If the mixture cannot be retained when it contains valerian, brandy or whisky may be substituted. He still further insists upon the internal administration every 2, 3, or 4 hours, according to the urgency of the symptoms, of 0.015 gm. ($\frac{1}{4}$ gr.) doses of spartan sulfate, with from 0.24 gm. to 0.36 gm. (4 gr. to 6 gr.) of caffeine. The alcoholic stimulant upon which he depends is

Tokay wine. This is administered in tablespoonful doses every half hour, and is given with the ethereal stimulant when due. Occasionally it is necessary to use high rectal injections of coffee and whisky, and hypodermic injections of ether, sterilized oil, and camphor during periods of collapse, with subcutaneous or intravenous injections of saline solution. However desperate the condition, he recommends persistence in the use of the diffusible stimulants, always administered with the idea of meeting the fading effects of the preceding dose. [C.A.O.]

7.—Ocular Complications of Mumps.—Abscess of the eyelids, conjunctivitis, keratitis, iritis, inflammation of the lacrimal glands, paralysis of the accommodation, amblyopia, optic neuritis, and neuroretinitis are some of the conditions mentioned by J. H. Woodward as complicating parotiditis. He reports in detail a case of optic neuritis in a girl of 11, which has now been under observation 18 months. [C.A.O.]

Medical News.

January 9, 1904. [Vol. 84, No. 2.]

1. The Mortality of Appendicitis. FREDERICS DENNIS.
2. The Relation of Proteids to Edema in Marantic Children; with Urinalyses in Infantile Diarrhea. PALMER A. POTTER.
3. Diagnosis of Gallbladder Diseases. J. THOMPSON SCHELL.
4. The Diagnostic Value of the Röntgen Rays. CHARLES LESTER LEONARD.
5. The Value of Climate in Genitourinary Tuberculosis. W. H. PRIOLEAU.
6. Sea-sickness. WILLIAM F. WAUGH.

1.—Mortality of Appendicitis.—Frederic S. Dennis says the question is, can the mortality of appendicitis be reduced by immediate operation in all cases, or by delay in mild cases, and the removal of the appendix after the attack has subsided. It has been proved by the accumulated experience of surgeons that interval cases have practically no mortality; and that operations during an attack, even though early, have been attended by some mortality. Dennis believes the only safe plan is to decide each case upon its merits. The mortality in appendicitis in all cases under medical treatment is about 16%, with 30% of relapses, while in diffuse suppurative peritonitis it is almost uniformly fatal. The mortality in all cases under surgical treatment is about 4%, and with no relapses. He holds that many cases demand immediate operation, but in any instance, if the patient is not materially better after the first 36 hours, operation should be performed; to wait longer than this increases the mortality. Fowler has demonstrated that operation in 48 hours in 127 cases, 83% recovered; after the fourth day there were 60% recoveries; on the fifth and sixth days, 58%; on the seventh to the eighth day, 50%, and on the ninth to tenth day, 33%. The value of the early operation depending upon the condition of the patient in 48 hours after the onset of the attack is thus obvious. The writer's mortality in his last 119 cases of appendicitis, irrespective of the kind of operation or of any special plan of treatment, was slightly over 1.5%; the 2 patients who died were moribund at time of operation. In the present paper he reports having operated upon 11 consecutive cases of acute perforated gangrenous appendicitis with general peritonitis. All of the patients recovered, in spite of the fact that the mortality heretofore in these cases has ranged from 31% to 91%. Concerning the further lowering of the mortality in appendicitis, Dennis says it can be reduced only by a hearty, cordial cooperation of both physician and surgeon, and when these relations are established, the deathrate, small as it is, will be still further reduced. [A.B.C.]

2.—Relation of Proteids to Edema in Marantic Children, with Urinalyses in Infantile Diarrhea.—P. A. Potter has examined the urine of a number of children with acute fermentative or infectious diarrheas. The idea in taking acute cases was to avoid mistaking degenerative kidney changes from long wasting illness for acute inflammatory processes, due to diarrhea itself. Those in whose stools Shiga bacilli were found or whose blood agglutinated these, were chosen to represent infectious forms, because the specific infectious nature here is considered proved. The writer lays special emphasis on cases marked by edema, because of their rarity, the different theories as to etiology, and the absence of any regular and previously efficacious treatment. Of 12 cases of marked diar-

reha, with high temperature, great prostration, and blood or mucus in the stools, only one showed a mere trace of albumin. Indican was found in the urine of two. Hyaline casts were found in two other specimens from children under 4 months, and consequently have little significance. In 4 Shiga cases there was no albumin nor evidence of renal disturbance. Of 6 cases of diarrhea with edema, 5 recovered. This was due to disregarding the diarrhea in the treatment and increasing the strength of the proteids in the food. In the first case the food, which had been plain barley water, and later contained by the addition of 4% milk, 75% of fats and proteids, was abruptly changed to a mixture containing 2.5% of proteids and fats, and in 16 hours the edema had entirely disappeared. Herter, with whom the writer agrees, thinks the edema due to involvement of the sympathetic nervous system from severe depression. Proteids are needed, notwithstanding their locally irritant effect on the intestines. Since diarrhea is not accompanied by kidney disturbances, alcohol is not injurious if needed for stimulation. [H.M.]

3.—Diagnosis of the Gallbladder Diseases.—J. T. Schell says, to assert that the general diagnosis of cholecystitis and cholelithiasis is easy and that the position of the calculus may in all instances be determined is an acknowledgment of inexperience with intraabdominal lesions. He discusses acute catarrhal cholangitis, suppurative cholangitis and the symptoms which appertain to each. Gallbladder diseases are to be differentiated from appendicitis, acute pancreatitis, perforating ulcer of the stomach or duodenum, gastralgia, nonperforating gastric ulcer, intestinal colic, carcinoma of the gallbladder and movable kidney. The best means for differentiating these conditions forms a series of discussions by the writer. The Röntgen rays have proved of but little avail in the diagnosis of gallstones. [A.B.C.]

4.—Diagnostic Value of Röntgen Rays.—Charles Lester Leonard says: The use of the Röntgen rays does not wholly eliminate the personal equation or the skill of the observer. Sufficient of these elements enter into the final results to frequently render them far from accurate. Equally good results should not be expected from the expert and the novice. The necessary knowledge and technic are not readily acquired, and earnest study is demanded of the student if he would learn to avoid errors. The writer confines himself to a discussion of the value of Röntgen rays in calculus nephritis and ureteritis. His conclusions are based on a study of 300 cases. The advantages demonstrated are a greater accuracy than in other methods of diagnosis; a freedom from the dangers and inconvenience of exploratory operation, vesical examination and ureteral catheterization; the definite locating of all calculi, giving their size, number, position, etc. An analysis of the 300 cases shows that calculi have been found in 86, or over 28%; that in 46 of these cases, or over 50%, the calculi were in the ureter; that in 19 of the cases of ureteral calculus the patients passed the calculi after expectant treatment had been suggested as the result of the Röntgen ray examination. The positive diagnosis has been confirmed by operation in all cases operated upon except 5. In two of these the operation was delayed more than a month, and it is probable that the calculi, which were small, passed. The negative diagnosis has been found as accurate as the positive. This diagnosis has been found correct in 45 cases that have come to operation after the negative diagnosis had been made. In 1 case, previously reported, a large calculus was found, the error being due to faulty technic. The total combined errors in both positive and negative diagnoses has been less than 3%. Frequently a pathologic condition of the tissues of an organ may be recognized in the photograph as well as the discovery of a stone. [A.B.C.]

5.—Value of Climate in Genitourinary Tuberculosis.—W. H. Prioleau maintains that equally beneficial results may be obtained in patients suffering from tuberculosis of the genitourinary apparatus as in those suffering from pulmonary tuberculosis or other tuberculous affections, provided, the genitourinary tuberculosis is recognized early, and equally as early as other cases sent to an appropriate climate. The principal reasons for the beneficial results obtained in pulmonary tuberculosis upon change of climate is the fact that the disease is recognized in its incipency, whereas in genitourinary tubercu-

losis the condition is quite the reverse so far as recognition is concerned. If a patient presents himself suffering from some genitourinary disease, especially if the symptoms be such as would appear in incipient tuberculosis of that tract, the physician, unless an expert, would probably think of almost every other disease to which that part of the body is liable before tuberculosis, consequently, early diagnosis of genitourinary tuberculosis is very rare. Extremes of climate are unsuited to such cases and they usually do best in an equable climate at a moderate elevation just as do cases suffering from pulmonary tuberculosis. At no time should a patient with tuberculosis of the kidney be sent to an extreme altitude. The increased heart's action caused by the elevation adds more work to the already inflamed kidney and thus inhibits the benefit which might otherwise accrue. Accompanying the change of climate should be a proper regulation of the patient's diet. [A.B.C.]

6.—Sea-sickness.—W. F. Waugh believes that if sea-sickness is due to vasomotor splanchnic paresis, atropin and strychnin are indicated. He advises giving atropin, gr. $\frac{1}{100}$ every 10 minutes until slight dryness of the mouth is felt, and repeating when the dryness begins to subside. Strychnin, gr. $\frac{1}{4}$ should be given every 10 minutes until the pulse has its normal tonicity, and thereafter just enough to sustain this effect. These alkaloids may be taken in hot water by mouth. [H.M.]

EDITORIAL COMMENT

The Diagnosis of Acute Tuberculous Rheumatism.—The diagnosis of acute tuberculous rheumatism is often difficult and one is frequently placed in a position of making a diagnostic error. In children this is more likely to happen on account of the difficulty experienced in obtaining correct answers to questions. An osteomyelitis, especially when localized near the epiphyses and showing itself in several points at the same time, may give rise to many mistakes, but under these circumstances one should take into consideration the intensity of the general symptoms, the rise in temperature, the marked typhoid condition, and rely above all on the findings given by a minute examination of the skeleton. It is however, with acute articular rheumatism that the acute tuberculous form is more frequently confounded, because in the latter affection its polyarticular manifestations simulate the ordinary acute type, while clinically they closely imitate each other. The tuberculous form however differs by the rapidity with which it becomes localized in a joint, by the absence of any effect from the administration of sodium salicylate or the coal-tar products, and above all by its tendency to give rise to plastic products, often resulting in ankylosis. A point to be noted in the differential diagnosis is the character of the pain. In the infectious pseudorheumatism, due to Koch's bacillus as in all forms of arthritis for that matter, the greatest pain will be found by exerting pressure over the joint itself, while in acute articular rheumatism the periarticular parts, tendon sheaths, periarticular serous bursas, articular ligaments and tendons will give rise to the pain. It has been pointed out by Lasègue that in acute articular rheumatism there is no intra-articular pain but the fibrous tissue and bursas and serous coverings of the tendons are more involved than the synovial membrane of the joints. He gave as a proof of this, the possibility of giving passive motion to joints so afflicted, without provoking suffering to the patient, if the latter could be made to relax the muscles going to the joint thus immobilized. A differentiation with true acute articular rheumatism having been made, it is necessary in order to complete the diagnosis, to look for the cause of the trouble, a task often long and difficult. If however, the patient has never been the victim of gonorrhea or former puerperal infection nor of any infectious process susceptible of producing joint manifesta-

tations, one should always think of tuberculosis. Should the patient give an hereditary or personal history of tuberculosis, or should he show lesions of a tuberculous nature, it is both logical and prudent to connect the joint affection with Koch's bacillus. Cytodiagnosis, peritoneal inoculation in the guinea-pig of the fluid obtained from the joints and cultures made from it, will result in settling a faltering diagnosis.

REVIEW OF LITERATURE

The Relation of the Arterial System of the Bones to Inflammatory Areas of that Tissue.—E. Lexer¹ concludes that tuberculous areas usually originate from infected emboli or from collections of bacteria in the circulation, both becoming localized in the epiphysis or the metaphysis, although the process may begin in the diaphysis as a result of an embolus. The shaft tuberculosis can take its origin as well from an embolus as from a deposit of bacteria that have suddenly acquired virulence. The lesions in the diaphyses are explained upon anatomic grounds: soon after the nutrient artery enters, it divides into many branches in which emboli become lodged. The tuberculosis following injuries to bones is dependent upon the awakening of a latent process or upon the accidental deposit of an embolus or a collection of bacteria. The suppurations caused by the staphylococcus, streptococcus and pneumococcus also have their sites in the ends of bones, and are due to emboli in instances. The marrow phlegmon of nontraumatic origin is due to deposits of virulent pyogenic bacteria or to emboli. The relation of trauma to the development of suppurating osteomyelitis Lexer explains in 3 ways: The cocci circulating in the blood lodge at the injured point where the resistance has been reduced, the influence of the trauma upon the bactericidal action of the marrow, the trauma may awaken an old latent process. The predilection of both tuberculosis and suppuration for young bones is due to its vascularity and also to the histologic nature of the young bone marrow. [J.F.]

Treatment of Sciatica.—O. Hartmann² recommends stretching of the sciatic nerve for sciatica. He practises massage and hyperflexion of the limb for some time; if unsuccessful, he operates. [E.L.]

Dietetic and Drug Treatment of Tuberculosis.—D. L. Smith³ gives the results of treatment in the Manchester Sanatorium. Creosote, guaiacol, and arsenic were tried with varying effect. Urea had no influence at all on the course of the disease. Diet was of paramount importance, and especial stress is laid on a meat diet. This latter must be modified for patients with gastric disturbances. The object is not to increase the amount of fat on the individual, but to make him solid and robust. A gain in weight may occur without improvement of the pulmonary condition. [B.K.]

Relation of the Boas-Oppler Bacillus to Lactic Acid Fermentation.—G. Sandberg⁴ finds that the predominance of the "long" bacilli, described by Boas and Oppler, in certain diseases of the stomach, is due to the fact that these bacilli possess a special resistance to the higher lactic acids. This resistance is not even second to that of yeast. They may therefore flourish after all other organisms, which form lactic acid, have been destroyed. The fundamental type of this bacillus is a short rod; but it develops into a long form as soon as its ability to form lactic acid is fully developed, or when lactic acid has been produced through the agency of other bacteria. The long and short varieties produce characteristic colonies, between which certain experimentally produced transition forms may be placed. The short variety may be experimentally transformed into the long, and vice versa. [B.K.]

Negative Widal in Newborn, of Typhoid Mother.—G. B. Allaria and C. Bozzolo⁵ show that the *Bacillus typhosus* may be recovered from the spleen and other organs of the newborn on necropsy, when before its death the Widal had been negative. Other cases (4 out of 11) show a positive reaction at varying days following birth. Sooner or later the reactive pos-

⁵ Il Policlino, Rome, October 24, 1903.

sibility is lost, apparently. In 2 cases the placental blood gave a positive and the blood of the newborn a negative reaction. There is some relation of agglutinative power shown to the period in gestation when occurred the typhoid complication. The views of Staebli oppose those of Achard and agree with Widal and Sichert in the matter of transmission as seen in tests on animals. The specific gravity of fetal blood is known to be less than after birth, as is the relative quantity of fibrin. The authors point this out as the most important of several differences, and as bearing on the solution of the questions at issue. [T.H.E.]

GENERAL SURGERY

MARTIN B. TINKER

EDITORIAL COMMENT

The Radical Cure of Bunions.—Bunions, next to corns, are probably the most common of the various causes of foot discomfort, and in persons whose occupations require them to be constantly on their feet they may cause actual disability. The term is generally used to denote a painful swelling which frequently grows over the inner aspect of the ball of the great toe. In the first stage there is a partial outward dislocation of the great toe, the deviation from the middle line being caused almost always by faulty fitting shoes which are now commonly worn. Most shoes on sale, no matter how broad the toes and supposedly sensible they are, crowd the great toe outward and thus make the base of the toe more prominent and subject to abnormal pressure. By placing the inner side of the foot of a healthy child against a straight edge it will be seen that the inner border of the foot forms almost a straight line from the toe to the heel. Few modern shoes are made with a straight line from the heel to the toe though there has been much improvement in foot-wear of recent years. The abnormal pressure over the base of the great toe forms a bursa and frequently there is a chronic periosteitis which causes the head of the metatarsal bone to enlarge. Pressure on the bursa makes it sensitive and often intensely painful. Very few doctors are consulted for bunions and it must be confessed that this is partly because many do not understand their proper treatment, indeed, the subject is given most inadequate attention in many of the most popular modern textbooks on surgery. If physicians appreciated the importance of proper foot-wear as emphasized by Sampson in perhaps the most important paper¹ which has appeared on this subject they might do much to prevent numerous painful affections of the feet by using their influence to introduce proper footwear and if people were provided with suitable shoes from their earliest years there would be no necessity further to discuss the treatment of bunions. Taken at an early stage, hallux valgus, which precedes the formation of bunion, may perhaps be partly corrected by apparatus, but toe posts, springs and levers which are used to prevent or correct such deformities are of use only when the condition has not passed the early stage. Freeland,² in a recent monograph, believes that of the numerous operations which have been introduced to remove the boss of bone which gives rise to bunion none gives such uniformly good results as excision of the head of the first metatarsal bone. The relief from pain, restoration of function and reduction of deformity which follow are striking. This method is also recommended by Rose and Carless in the latest edition of their "Manual of Surgery." While palliative or less radical measures may be tried and may give relief in many cases, we believe that excision gives far the more satisfactory results in the treatment of very bad cases of bunion. We are surprised that this method is not mentioned in several of our modern American textbooks of surgery.

REVIEW OF LITERATURE

Excision of the Cecum.—F. T. Paul¹ reports 3 cases. The first was a man of 32, who had suffered for the past 6 months from colicky pains, flatulence, dyspepsia, and the other symptoms of progressive partial obstruction. Operation was performed, an incision being made over the cecum. The latter was found infiltrated with malignant disease. This, together with the lower end of the ileum and the whole of their attached mesentery, was removed; the ends of the bowel were brought out, and glass tubes inserted. The result was unfortunate, sloughing of the bowel occurring owing, perhaps, to too much of the circulation having been cut off. The next was a patient of 53, who looked much older. His symptoms were of the same type as in the preceding case. A soft tumor could be detected in the region of the cecum, which the operation proved to be a cancerous condition of that pouch. It was excised, and a glass tube inserted. The patient's condition was good for a few days, when he took a turn for the worse, and died from exhaustion, 3 weeks after operation. Necropsy showed the wound had healed perfectly about the stump. The third patient was a woman of 51. Her symptoms were again of the same general type. A large movable tumor could be detected in the cecal region. Laparotomy was performed, the cancerous cecum excised, and the patient made a good recovery. Attention is called to the fact that in these cases, as well as in malignant obstruction anywhere in the bowel, symptoms as a rule appear only after the tumor is of such size as to offer mechanical obstruction to the fecal current. Unfortunately, at such time the case has progressed so far that the condition is almost hopeless. [A.B.C.]

Sarcoma of the Undescended Testicle.—M. N. Shewandin² reports the result of a microscopic examination of a tumor originating in an undescended testicle. The growth revealed itself as a sarcoma, and the author remarks that the majority of growths of the retained testicles are sarcomas, with a malignant tendency, usually appearing in middle-aged men and ending fatally in most instances. These remarks apply to the testicles retained within the abdominal cavity, which location is about 5 times less frequent than the inguinal. When dealing with an abdominal growth of obscure origin we should always bear in mind the possibility of a retained testicle. The author also discusses the tumors of the testes in general. [L.J.]

Surgery of the Stomach in Nonmalignant Conditions.—A. B. Mitchell³ reports having operated on 12 patients for perforating gastric ulcer, with 8 recoveries. He reports also in some detail operation in 6 instances for hour-glass stomach. There were 5 recoveries, and one death from shock. His work in these cases illustrates 2 methods of dealing with this condition; (1) gastrogastrostomy, which he has found safe and efficient, but has the disadvantage of leaving an abnormal double-barrelled stomach; and (2) gastrojejunostomy, which is only applicable to cases in which the lower pouch is very small and the pylorus is involved in the adhesions. The author also reports operation in 6 instances for dilated stomach, due to pyloric obstruction, nonmalignant in character. With these cases the mortality was high—3 of the patients dying,—one death was chargeable to the operation, again 6 other cases are reported in which operation was done on the stomach, for various purposes, such as adhesions, excision of gastric ulcer, etc. All the patients recovered. [A.B.C.]

The Dangers of the Trendelenburg Position.—P. Kraske⁴ recognizes the value of this position in numerous operations on the pelvic and abdominal organs; but he has also found certain dangers to be connected with it. In persons with degenerative changes in the heart muscle, the high pressure of the column of blood in the inferior vena cava may produce an acute, irreparable dilation of the heart. In persons with a large amount of fat in their tissues, mesentery, and omentum, a marked and permanent displacement of the viscera may be produced, that may lead to intestinal obstruction. The pressure of the heavy viscera against the liver may produce stasis of the portal circulation, with consequent gastric hemorrhages. [B.K.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

EDITORIAL COMMENT

Local Edemas in Pregnancy.—The eclampsia and icterus which sometimes manifest themselves as consequences of the occasional autointoxications of pregnancy are well known to all experienced practitioners to rank among the most serious complications of that condition. The characteristic tint of jaundice can hardly be well mistaken for an indication of anything but what it pathologically indicates; but the *partial* edemas which sometimes inaugurate the onset of renal disorder, functional or organic, occasionally display themselves in a manner which proves highly misleading. Their occurrence and the causes which lead to such development have recently received a good deal of attention from some of our French confreres. In the early part of the past year, M. Budin communicated to the Obstetrical Society of Paris a paper which dealt with the subject of "Partial Edemas in the Puerperal State," and just recently Dr. Lop has reopened the discussion of the same subject. In one of the cases observed by the latter, there developed, in the course of pregnancy, a persistent edema of the back of the right hand; and in the other, of the eyelids of the right side. Those appearances led to an examination of the renal secretion in each case, and there was discovered a notable quantity of albumin, with some indican, and a marked degree of hypoazoturia. The liver was in each case enlarged, and there was a subicteric tint of the cutaneous surface. The condition of the eyelids in one of the cases had led to the mistaken diagnosis of a local lesion of the visual apparatus. It is interesting to note that the patient who presented the edema of the eyelids was observed in 2 pregnancies; in both the eyelids of the same side were affected, and in one of the pregnancies there was also edema of the back of the right hand, which had been attributed to rheumatic exudation. There was also dyspnea and some other less significant coexisting symptoms in both cases. In a third case observed by Dr. Lop, the patient presented palpebral edema, and also edema of the lobule of the ear on the right side, followed by puffing of the back of the hand and fingers on the left. Some little albumin and a good deal of biliary pigment were found in the urine. Rest, a milk diet, and the use of saline purgative brought the pregnancy in each case to a happy termination. Drs. Budin and Lop both attribute those phenomena to neurovascular disorders, produced by introduction of the toxins of puerperal infection into the renal circulation. Having regard to the possible mistakes of diagnosis in such cases, and the very serious results which are prone to ensue, we must regard the communication as a very important one.

REVIEW OF LITERATURE

Four Cases of Eclampsia.—Dr. Windisch-Odon¹ reports 4 cases of eclampsia in which morphin was given to control the nerves, hypodermoclysis of hot normal salt solution and warm packing to induce profuse perspiration. In 3 instances the treatment was successful; but in 1 case in which the profuse saline infusion and warm pack failed to induce perspiration the result was fatal. And he concludes that in those cases in which by means of hot saline infusion with warm packs and baths, abundant perspiration is induced, with corresponding use of morphin and early ending of labor under anesthesia, the prognosis of eclampsia is essentially improved. [w.k.]

Extrauterine Gestation.—H. Croom² says that primary abdominal and ovarian pregnancies are only curiosities so far as the general practitioner is concerned, and devotes his entire paper to the consideration of tubal pregnancy. This condition he asserts can be diagnosed before rupture has occurred. The important signs are: 1. The subjective signs of pregnancy. 2.

There is a long interval between extrauterine pregnancy and the pregnancy which precedes it. 3. There is a history of some uteroovarian disease. 4. What is called "disordered menstruation." This is a misnomer, the condition being generally that of amenorrhea for 1 month, and then irregular hemorrhages every 10 or 14 days. 5. Localized pelvic pain. 6. Vaginal examination reveals, on one or other side of the uterus, a cystic swelling, sensitive and pulsating. 7. The expulsion of the decidua at the end of the third month is one of the most striking signs, if not the pathognomonic sign of extrauterine pregnancy. Croom also considers the symptoms and treatment of rupture. [A.G.E.]

The Septum Stitch in Prolapse Operation.—R. Gersuny¹ describes an operation for prolapse, in which a longitudinal incision is made in the anterior vaginal wall in front of the cystocele, which is loosened by blunt separation; then after introversion of the bladder, the defect in the septum is lessened or entirely closed by a pursestring suture, and the longitudinal incision also closed with interrupted sutures, strengthening and supporting the septum. [w.k.]

Blood Alterations During Pregnancy.—G. Resinelli and Caruso² consider that any normal pregnancy, if favorably managed as to diet and hygiene, should present no diminution in number of red blood cells; the percentage of hemoglobin may slightly decrease. Anemia is pathologic during pregnancy. There may be a hydremia proper to normal gestation, which is an integral part of blood alterations incident to that process and absolutely physiologic. These changes of the blood bring about a condition of lessened resistance. With this, any disturbance of metabolic equilibrium may develop into an actual anemia. And, similar to renal, cardiac, or hepatic insufficiency, there may occur a hematopoietic insufficiency. Simple anemia ordinarily brings no difficulties; progressive pernicious anemia is grave. The writers advise induction of premature labor in case of the latter. Some writers suggest oophorectomy as a final course in obstinate cases. Merletti and Raineri speak of the urobilinuria as evidence of modified hematopoiesis. They find a different coagulability of the maternal blood, due to a deficiency in calcium salts. Retention of a dead fetus brings about a lessened coagulability of the maternal blood, and is partly diagnostic, according to Gelli. Mangiagalli does not advise induction of labor prematurely in progressive pernicious anemia, believing that causes of the disease lie in the ovarian origination of toxins, which are prejudicial to the blood. The results of interference are not satisfactory. Ferrari suggests bovine bone marrow and claims good results. [T.H.E.]

Eclampsia with Enormous Placenta.—R. Koenig³ reports a case of eclampsia in which the placenta had assumed very unusual proportions, weighing 1,620 g. The literature accessible to the writer indicates that a large placenta usually accompanied a large fetus, and chiefly occurred in multipara with large joints and flabby uteri. But in the case reported the abnormal size of the placenta seemed to be independent of fetal condition since the placenta weighed half as much as the child. [w.k.]

Combined Use of Finsen Light and X-ray in the Treatment of Uterine Carcinoma.—G. G. Hopkins⁴ believes that in the combined use of the Finsen light and the x-ray, the principal dependence being the Finsen light, he has devised a very satisfactory method for the cure of uterine carcinoma, especially when that disease originates in the cervix. Great caution must be observed in the use of the x-ray, particularly in recurrent cases in which hysterectomy has been done. He has found that an hour's exposure to the Finsen light and 5 to 8 minutes exposure to the x-ray is a good proportion in which to employ the 2 agents. He describes very carefully an apparatus for carrying the tubes, so constructed that the patient need not be placed in a constrained position during treatment. None of the many substitutes for the Finsen light has given as good results as the original apparatus. The clinical histories of cases is to be given later, but the results have been such as to place this method above any other yet devised for the treatment of uterine

carcinoma. Hopkins believes that we may hope to cure the majority of these cases, as he has not yet seen a case not benefited, and in all but one, the indications are that cure has been accomplished, though the time (2 years) is too short to claim that cure is perfect. The result in cases recurring after operations of greater or less magnitude is not so good. [A.G.E.]

Recurrence of Ovarian Cysts.—J. D. Malcolm¹ reports 4 cases in which a cystic ovarian tumor, which was not malignant, developed after a similar growth of the ovary on the same side had been removed. In these cases the tumors removed were, in fact, cystic growths of some portions of ovarian tissue, which were left behind at the first operation. The newgrowth in all the cases developed in the broad ligaments where the ovarian tissue would be, if any were left at a previous operation. Cases 3 and 4 illustrate another somewhat rare point, namely, that an innocent growth developing in the neighborhood of the uterus after the menopause, may bring about discharges of blood from the endometrium, just as ovarian tumors growing before the menopause may induce a very free menstruation, which may lead to an erroneous diagnosis of uterine fibroma. [W.K.]

Diabetes and Surgery.—Otfried O. Fellner² relates the history of a woman of 40, who, after going through 2 normal pregnancies, developed diabetes, then had pain and an abortion followed by excessive bleeding, for which curetment was done. Fellner believes that in all probability there was some relation between the abortion and the diabetes. The patient was operated upon twice for an abscess of the "scheiden gewalbe," after which the urine cleared up. He reports a second case in a woman of 36, who had conceived 5 times and aborted 3 times. After the last abortion she developed an endometritis, which required curetment. Later a myoma was successfully removed, but 4 months later she developed diabetes. Fellner differentiates 2 groups of cases: (1) Those in which surgical conditions follow diabetes; (2) those in which the diabetes is the result of diseases of the genital organs. The literature of this subject is fully reviewed. [J.H.W.R.]

Puerperal Eclampsia before Delivery.—J. Lithgow³ reports 2 cases of eclamptic convulsions before delivery, and is convinced from his experience that in immediately emptying the uterus the obstetrician is doing the best for both mother and child. [W.K.]

The Vaginal Route in Ectopic Pregnancy.—W. W. Preobrajensky⁴ has made a thorough study of Professor Ott's method of illuminating deep cavities, and comes to the conviction that the method considerably facilitates vaginal operations, giving them many advantages of their own. The entire operation can be performed under control of the eye; any source of bleeding can easily be found and checked, a feature specially valuable in the wellknown tendency of ectopic pregnancy to hemorrhages. Therefore he prefers the vaginal route in all stages of extrauterine gestation under 4 to 5 months. The best course is to perform posterior colpotomy, reserving anterior colpotomy only for special indications. The utmost conservatism is enjoined in regard to the tube, which ought to be left *in situ* whenever feasible. Formerly, the risk connected with the operation for extrauterine gestation often led to procrastination and disaster; the new method enables us to interfere with but little danger, and therefore every case of ectopic pregnancy should receive surgical treatment. [L.J.]

Successful Celiotomy for Ectopic Gestation with Forced Abandonment of Placenta.—Calderini⁵ reports such an occurrence with the delivery of a living child. An abdominal fistula has remained, but health of the mother and child is good. Pestalozza differs as to time of operative interference. The author feels justified by results. The placenta could not be removed, however, on account of uncontrollable hemorrhage. Ghezzi gives 2 cases in one of which a macerated fetus was removed, in the other the mother succumbed from shock. Ten successful cases are on record in Italy since 1814. [T.H.E.]

TREATMENT

SOLOMON SOLIS COHEN

H. C. WOOD, JR.

L. F. APPLEMAN

REVIEW OF LITERATURE

Organotherapy in Arterial Hypertension.—H. Huchard¹ points out that among the hypotensive glands which may be used in arterial hypertension are the liver, thymus, testicle, ovary, and thyroid gland. Lancereaux and Paulesco have used thyroid extracts, and especially iodothyryn, in scleroderma, vasomotor troubles of the extremities, and in arteriosclerosis. The action of these preparations is sudden and rapid; it may be accompanied by weakness and collapse, and for this reason should be carefully watched. Huchard has been able to produce vasodilation by the administration of thymus gland. No unfavorable symptoms followed its use, while its action lasted for considerable time. Ovarian extract has been used at the time of menopause in patients who suffered from arteriosclerosis and high arterial tension. All means employed for the relief of high arterial tension should be accompanied by proper modification of the diet and other hygienic measures. As a result of the action of various animal extracts, it would appear that the normal vascular tone depends not only upon the myocardium, the blood and bloodvessels, but also upon proper glandular activity. [L.F.A.]

Local Uses of Hot Air.—Holländer has, since 1897, applied hot air to the treatment of lupus. According to his opinion, hot air acts by reason of its antiseptic and hemostatic power. He employs either absolute or relative cauterization. The area affected by lupus becomes supplied by newly formed vessels and forms a distinct prominence above the level of the healthy tissues. In the course of several days the healthy skin resumes its normal aspect, while the diseased areas begin to undergo necrosis. A long metallic rod terminating in a point is pierced by a central opening, through which a current of air may be passed by means of a rubber bulb. By utilizing a source of heat sufficiently intense, the current of air, which, after having traversed the opening in the incandescent metallic rod escapes through the free opening, may attain a temperature of more than 300° C. (572° F.). For a long time dentists have employed hot air by means of an exceedingly simple apparatus. This consists essentially of a bulb and a metallic tube provided with a wooden handle to which the bulb is adjusted. The tube is continued in a convoluted form into a closed metallic sheath, and ends in a point. It is contained in a hard-rubber case, from which only the pointed extremity projects. The tube is heated for several minutes over an alcohol lamp at the point where the convoluted portion is contained in the sheath, and is then placed in its case. The bulb is then compressed, and the air is heated in passing through the convoluted tube. F. Jayle has employed aërothermotherapy at the Hôpital Broca in a certain number of cases of simple and specific ulceration situated in different portions of the body. He experienced complete failure in some cases, amelioration in others, and favorable results in still others. He employs an ordinary thermocautery, with certain modifications. The air from the bulb divides into 2 currents; one portion supplies the thermocautery and maintains it at red heat, the other enters the sheath and is heated in passing over the cautery. Each compression of the bulb acts at once upon the thermocautery and upon the current of air. By this means a current of hot air is provided at the extremity of the thermocautery, which is thus converted into a sort of aërothermogen. By providing the sheath with a conical attachment having an orifice varying from 0.5 mm. to 1 cm. in diameter, different temperatures can be obtained, which are almost constant for each opening. The current of hot, dry air carries with it the products of combustion of the thermocautery, so that if one wishes to have pure air he may substitute for the concentric sheath a tube placed in juxtaposition with the thermocautery. This becomes heated by contiguity, and the air that passes through it becomes heated in its course. Balzer successfully employed the method of Holländer in the treatment of chancroid. Before him,

Bourgeois had applied hot air in the treatment of infectious ulcers of the cornea. Gautier and Larat, and after them Löwenberg, have treated ozena with hot air. A current of compressed air is passed through water charged with medicinal substances into a short convoluted tube connected with a flexible metallic tube, the free extremity of which, finally, is provided with another short rubber tube and a glass nasal canula of special form. The source of heat may be electricity, gas, or alcohol. A lamp placed beneath the convoluted tube is sufficient for heating purposes. E. Larue Vansant (1897) employs insufflations of hot air in the treatment of otorrhea, otalgia, eustachian catarrh, and certain other affections of the nose, the pharynx, and the larynx. For the relief of the pain (headache) that is so frequently observed when the openings of the sinuses in the nasal cavity become obstructed, the insufflation of hot air is often quickly effective. Vansant uses an instrument in the form of a revolver, which the physician holds in his hand by the curved end. At the point of union of the handle and the straight portion there is a bulbous enlargement, which may be heated by means of an alcohol lamp. The air is conveyed to this point by means of a bulb or a compressed air reservoir. It is heated at this point, and, with the aid of a capillary tube adapted to the anterior portion of the instrument, is directed to the diseased spot. Vansant must be given credit for the systematic use of superheated air in the treatment of affections of the upper air passages and of the ear. The writers who have followed him have either modified his instrument or have defined more exactly the indications for the method. Thus, Amberg, in 1893, successfully employed aerothermotherapy in the treatment of ozena and various other nasal affections. Hessler, in 1900, following Andrews, employed hot air without much success in the treatment of chronic supuration of the ear. Lately Lermoyez has repeated these attempts, and concludes that aerothermotherapy yields the best results in cases of spasmodic rhinitis, congestive rhinitis, hypertrophic rhinitis, hydrorrhea with nasal obstruction, rhinorrhea, sneezing, asthma, nasopharyngeal catarrh, otalgia, tubal and tubotympanic catarrh with deafness, vertigo, nausea, or ringing in the ears. The cure is permanent, and the condition is not one merely of transitory amelioration. Acute coryza and hay-fever may also be advantageously treated by this method. Lichtwitz has obtained good results in cases of spasmodic and subacute rhinitis. Aerothermotherapy, so-called, undoubtedly yields good results in the treatment of certain affections of the nose; but Tissier does not think that this should be credited to aerotherapy. He would prefer to use the term "thermotherapy," because the quality of the air is of little importance; it is the temperature alone that is effective. Similar comment may be made concerning the application of superheated dry air to the extremities or other portions of the body, inclosed in special "cabinets," "cylinders," "thermophors," and the like. Tallermann and others use very high temperatures—400° F. (205° C.)—in these apparatus; principally for the treatment of affections of the joints, but also to induce perspiration and to influence metabolism in certain diathetic disorders, such as gout, rheumatism and the like. W. T. Hedley has not exceeded temperatures of from 60° C. (140° F.) to 100° C. (212° F.). He has employed hot air with rapid relief of pain in the treatment of subacute articular rheumatism and in cases of chronic articular rheumatism.—[Paul Tissier, "Aerotherapy," Blakiston, 1903.]

Accidents Due to Lumbar Puncture.—Lumbar puncture is usually not accompanied by unfavorable complications.¹ It may be followed by pain in the legs, headache, vomiting, vertigo, and syncope, but these are not serious as a rule. When followed by fever and tachycardia in association with meningeal symptoms, the situation is grave, and death may occur. Henneberg reports a death from hemorrhage following a lumbar puncture. Andre Maystre² indicates the precautions that should be taken. The patient should be prepared as for a major operation. He should be given a purge and a diuretic, the diet should be light, and he should avoid all worry; after the operation the patient should be placed in bed

with his head low and allowed to remain in this position for 6 hours or more, according to the needs. Asepsis should be practised with scrupulous care. When the needle is withdrawn the cutaneous orifice should be touched with tincture of iodine or a thermocautery; a little collodion may be used to close the wound, and this in turn covered with a layer of cotton and a bandage which is left in place for 48 hours. The puncture is made in the lumbosacral region. Not more than 7 cm. to 10 cm. (2 dr. to 2½ dr.) of liquid should be drawn off, as larger quantities may lead to serious consequences. It should be withdrawn very slowly, never aspirating to hasten the flow. The face and the pulse of the patient should be watched, and at the least faintness or complaint the needle should be withdrawn. These precautions will reduce the complications to a minimum, but the operation should only be performed in urgent cases. This treatment may be used in cerebrospinal meningitis when hot baths seem to produce no improvement. Certain cases of cephalalgia due to Bright's disease are relieved by lumbar puncture. As a means of diagnosis it should be used only in indecisive cases in which a definite knowledge is necessary, and in such cases a consultant should be called. [L.F.A.]

Favorable results from collargolum per rectum are recorded by Dr. H. S. Loeb in Schlesinger's Division of the Franz-Josef Spital.¹ Sometimes the intravenous injection of collargolum was impossible, because of obesity or smallness of the vessels. Collargolum enemas of .14 gm. to .27 gm. (2½ gr. to 4½ gr.) in 75 cc. (2½ oz.) of distilled water were therefore given twice daily for 8 days, after a cleansing enema. This method was successfully used in sepsis, a puerperal infection, and thrombophlebitis following typhoid. In 4 cases the enemas had to be stopped, because of negative effects or because of complications. In 6 febrile tuberculous cases conclusive results were not obtained. The advantages of the rectal use are its safety and simplicity and the ease of increasing the dosage. Discussing Loeb's report, Dr. Frank and Professor Schlesinger held that collargolum is a most effective remedy for septic conditions. Schlesinger has seen in apparently hopeless cases cure follow its intravenous use. In his experience the rectal application is also effective. [w.e.] [These reports deserve attention. s.s.c.]

The Nernst Lamp for the Production of Ether Waves for Use in Therapeutics.—Wm. Rollins² states that of the 2 forms of electric lamps used most extensively for the production of ether waves the arc is the more suitable for the production of short waves. In this lamp the temperature is higher, making the proportion of short waves greater, as there is no glass covering to absorb these waves, as in the incandescent lamp. Rollins has experimented with Walter Nernst's lamp, in which a rod containing a preparation of zirconia is heated by an electric current. This lamp requires no glass covering, although it is supplied with one. Loss of short waves is therefore avoided. This light is suitable for use in therapeutic cabinets in which an even distribution of radiant energy is desired and usually obtained by the use of many incandescent bulbs, in some cases over 90. Another advantage over incandescent bulbs is that the consumption of current for the same number of light waves is greater, less of the current being converted into the longer heat waves. [L.F.A.]

Treatment of Furunculosis.—The patient should be ordered to drink a glass of purgative mineral water before breakfast for 3 or 4 days. At the end of this time he should be given fresh brewer's yeast; 1 teaspoonful in a glass of water before each meal. This must be continued for a week. The diet should be restricted; no pork and no wine or other alcoholic beverage should be allowed. His general health should be improved. Locally, the furuncles may be aborted by painting them with tincture of iodine or by the application of compresses dipped in camphorated alcohol. Gallois³ recommends a solution of iodine in acetone, as follows:

Metallic iodine 4 gm. (1 dr.)
Acetone 10 gm. (2½ dr.)

A cotton applicator should be dipped in this solution and applied to each of the inflamed points. A pimple which has

not suppurated will usually disappear by the following day. The remedy must be used with care, owing to its caustic action. [L.F.A.] [For ordinary staphylococci or streptococci infections of the skin, a 4% solution of formaldehyd is usually the best application—not painful and quite effective. S.S.C.]

Lactovegetarian Diet.—The suppression of meat from the diet necessitates the administration of vegetable articles which shall furnish the body with sufficient nutrient principles to maintain normal nutrition.¹ In establishing a milk-vegetable diet, it is necessary to include butter, sugar and certain farinaceous articles as these are of great caloric value. In cases of cardioarterial disease or in nephritis large quantities of milk should be given between meals to act as a diuretic and aid in the elimination of toxins. The following diet is recommended: For breakfast, beside milk, a little fresh butter and bread. At midday, two dishes may be given, the first of macaroni, pea-soup or an omelet souffle, which are the most nutritious foods; the second should be composed of less nutritious articles such as potatoes, carrots, turnips and cabbage. Fresh fruit and nuts are very beneficial. Fermented cheese should not be allowed. For dinner, soups containing turnips, onions, carrots, celery or cabbage may be given; these vegetables are rich in potash and act as stimulants to oxidation and as diuretics. These vegetable soups may be replaced by those containing milk and other farinaceous articles. After the soup, eggs, legumes and fruit may be given. A small quantity of Bordeaux wine may be allowed if the patient has been accustomed to some alcoholic beverage with his meals. [L.F.A.]

FORMULAS, ORIGINAL AND SELECTED.

Local Treatment of Leukorrhea and Gonorrheal Vaginitis.—

Cerevisin (*saccharomyces cerevisæ*) . . . 90 gm. (3 oz.)
Glycerin of starch (cold) 60 gm. (2 oz.)
Make into a paste.

This is recommended for persistent vaginal discharges (especially old standing cases), by Chapelle, of Paris. A portion of the paste made up in a ball about the size of a walnut, should be placed in the vagina, well up against the cervix, and retained in position by a tampon of absorbent cotton. The patient is sustained by liberal diet and tonics. Cerevisin is a pure form of the yeast plant, desiccated at a low temperature.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 8, 1904:

Changes in the Medical Corps of the U. S. Army for the week ended January 9, 1904:

ALLEN, First Lieutenant JOHN H., assistant surgeon, is granted leave for one month.

OWENS, GEORGE F., contract surgeon, having reported to the surgeon-general of the Army, is relieved from further duty in the division of the Philippines, and will proceed to his home, Upper Marlboro Md., for annulment of contract.

SPRINGWATER, SAMUEL A., contract surgeon, leave granted September 8 is extended one month.

O'REILLY, Sergeant First Class PATRICK, Cabana Barracks, Havana, Cuba, will accompany the troops leaving that station to Fort Barancas. Upon completion of the duty he will proceed to the Army General Hospital, Washington Barracks, for duty.

JOHNSON, Major RICHARD W., surgeon, will, in addition to the duties heretofore assigned him in connection with the Louisiana Purchase Exposition, St. Louis, Mo., supervise the sanitary conditions on the exposition grounds until April 1.

POLHEMUS, Major ADRIAN S., surgeon, extension of leave granted December 7 is further extended two months.

Orders of November 19 are amended to direct Contract Surgeon Victor E. Watkins to report to the commanding general, department of California, for assignment to duty in that department.

ENDERS, WILLIAM J., contract surgeon, will transfer the medical property at Fort Delaware to the post surgeon at Fort DuPont, and will then proceed to Fort Morgan for duty.

Changes in the Public Health and Marine-Hospital Service for the week ended January 7, 1904:

IRWIN, FAIRFAX, surgeon, detailed as member of Revenue Cutter Service retiring board, to be convened at Philadelphia, Pa., January 5, 1904.

ROSENBAUM, M. J., passed assistant surgeon, is granted four days leave of absence from January 1, 1904, under paragraph 189 of the regulations.

KORN, W. A., assistant surgeon, detailed as member of the Revenue Cutter Service retiring board, to be convened at Philadelphia, Pa., January 5, 1904.

AMESSE, J. W., assistant surgeon, is granted leave of absence, on account of sickness, for seven days.

ASHFORD, F. A., assistant surgeon, is relieved from duty at Chicago, Ill., and directed to proceed to Milwaukee, Wis., and assume temporary command of the service at that port.

BROCK, G. H., pharmacist, is granted leave of absence for one day.

MAGUIRE, E. S., pharmacist, is granted leave of absence for seven days from January 1.

Boards Convened.

Board convened to meet at the Marine-Hospital, Chelsea, Mass., January 11, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon R. M. Woodward, Chairman, Assistant Surgeon W. C. Rucker, Recorder.

Board convened to meet at Washington, D. C., for the purpose of considering revision of medical books on contract, and preparation of list of professional books, etc. Detail for the Board: Assistant Surgeon General L. L. Williams, Chairman; Assistant Surgeon-General H. D. Geddings; Assistant Surgeon-General A. J. McLaughlin, Recorder.

Changes in the Medical Corps of the U. S. Navy for the week ended January 9, 1904:

BEYER, H. G., surgeon, upon completion of board duty in connection with barracks, ordered to Boston, Mass., for special temporary duty, and thence to the Naval Museum of Hygiene and Medical School, Washington, D. C.—January 6.

PECK, A. E., assistant surgeon, ordered to the Pensacola—January 7.

ELMER, M. K., assistant surgeon, detached from the Pensacola and ordered to the Hancock—January 7.

Criticism of Dr. Kober's Statistics as to Disease and Drunkenness in the Army.—Several correspondents have written *American Medicine* in mild or vehement criticism of the figures given in Dr. Kober's article concerning the influence of the army canteen in the production of disease, etc., published in our issue of December 5, 1903. So far as pertains to temperance, this journal has always been outspoken in its advocacy. There are, of course, few or no greater sources of disease and degeneracy than intemperance, and every good physician will do all he can to lessen these by lessening the abusive use of alcoholic drinks. If prohibition were possible, we would seek to realize it by every means in our power. For that very reason, and trusting in the accuracy of the statistics given by so reliable an authority as Dr. Kober, we expressed our astonishment at the increased drunkenness, venereal and other diseases, etc., consequent upon the abrogation of the army canteen. But partisanship must not govern scientific opinion, and one must not be carried away by an irrational zeal for a silk banner with a resounding war-cry and in the name of patriotism desert to the enemy. This some of the over-zealous temperance people seem to be in danger of doing. If there is more disease, etc., from the canteen, then the canteen must stay abolished. But if the canteen decreases the evils, then it should be reestablished. There can be no question that as a result of the abolition of the canteen the statistical tables show an increase of drunkenness, vice, venereal diseases, desertions, etc., and a decrease of savings deposits. The figures have been verified, and with a single unimportant exception not affecting the result, and due to a typographic error, they have been found correct, and according to the official reports. We refer to letters in another column. Until falsity in the figures is proved, we cannot give further space for opinions in our columns.

Physicians should encourage temperance—and even teetotalism—this seems the certain trend of present professional opinion. The experience of certain English life insurance companies which we epitomized last year in several editorials make the lesson clear that longevity is much greater in the total abstainers than even in the moderate drinkers, and, of course, drunkenness is evil in itself, and a source of greater evils. The contention that alcohol is an essential part of a healthy diet, or

that it has any considerable food value is no longer supported by scientists or moralists whose opinion is of much value. That it helps the drinker to do work, physical or mental, is also disproved. Whether it contributes to "sociability" or not, and whether the kind of sociability it may encourage is of any value to the individual or to society is hardly a medical question. But that it is one of the great causes direct and indirect of many diseases, and especially of those most loathsome and impossibly controlled ones, which are called venereal; of this there can be no doubt in the minds of experienced medical men. The great function of the profession is to cure disease, but one still more binding is to prevent it. This is the solid and sufficient reason why the influence of the profession is more and more being thrown with all those sane and feasible agencies that make for temperance. But as scientists the methods we advocate must be governed by experience, and by the choice of the lesser evil, when the absolute good is found to be impossible, or when the attempt to realize it begets the very evil to be cured. The resolute support of the feasible reform—that by legal and educational methods—should not be lessened because of the extremism and prejudice which multiplies the abuse it blindly seeks to uproot by force and passion.

No Monopoly in the Manufacture of Diphtheria Antitoxin.—The newspapers for the past weeks have contained a great many articles and reports as to increased prices demanded by a trust, which is said to control the supply and to regulate the price of the diphtheria antitoxin made in this country. If this is true, or if it should become true in the future, the medical profession would be the first to stop it. There should not be any such a monopoly, nor should the price be made higher than will yield a just profit to the manufacturers of a pure and standardized product. From a letter published in another column, it would seem clear that the alarm is not justified. Certainly the truth as to a reported monopoly or "combine" can be ascertained, and just as certainly can the cost of manufacturing a trustworthy antitoxin be ascertained. Our correspondent says that the price has been lowered instead of raised, and that the erroneous report has been caused by the change in the strength of the preparation and the method of distribution. We would suggest the appoint-

ment of a committee of experts, medical men and pathologists, whose names would alone be a guarantee of confidence in their report, and who should at once investigate the facts and end a doubt, which is harmful alike to the manufacturer, the physician, the patient, and the community.

Corporations and Vaccination.—The order of the Pennsylvania Railroad requiring its employes to be vaccinated, should be followed by similar orders on the part of the transportation companies and other great corporations of the country. It is, when closely viewed, for their self-interest, and it is strange that a policy so good alike for the employer, the employed, and for the general public, should have been delayed so long. Were the large employers of labor of the nation to follow this policy it would be the grandest step toward universal vaccination yet made, and would undoubtedly be followed by an immediate lessening of the number of cases of illness and death from the disease. The men would be encouraged by the order to carry out vaccination in their families, and it would not be long before a condition of public sentiment would exist which would demand laws and rigidly enforce their execution for compulsory vaccination. America may be freed from the curse of the disease as perfectly as Germany, when she takes the same precaution. There can be no further parleying and let-alone with the antivaccinationists. One antivaccination journal editor says he has been producing nitric acid sores for over 15 years, and will continue to do so, to fool the doctors. The Boards of Health and the law should attend to such people.

To Prevent Pneumonia.—The increase of pneumonia is attracting the attention of some Boards of Health, and of all public-minded citizens. But in many places there are no boards and no public-minded citizens. The first rule for the prevention of the disease would be to make the people understand that though not as contagious as smallpox, it is nevertheless sufficiently so to render notification necessary, and proper precautions not to "catch" it, and to keep the system in such a condition of health that the germs cannot find a nidus. Of "corrupt and contented" Philadelphia and Pennsylvania, little may perhaps be expected. For another century our street cars will probably not be heated, our water not be purified, our streets not cleaned, nor the masses of filth, snow and ice in winter removed. The health of the people does not, of course, concern our political rulers. In Chicago the energetic commissioner keeps up his tireless crusade. In most of the nation there is silence concerning the matter. In New York the Board of Health is trying to instruct the people how they may individually avoid the disease. These are some of its *Don'ts*:

Don't stop treating a "slight cold" until it is completely cured.

Don't go into the cold air in an overheated condition.

Don't go out of an overheated room into the street without wrapping up.

Don't stay in an overheated room any longer than you can help it. A moderate temperature is more healthful.

Don't sit in an overheated car too tightly bundled up.

Don't drink too much.

Don't go without a proper amount of sleep; rest is necessary to keep the body in a proper state of resistance.

Don't hesitate to see the doctor. A step in time may save an undertaker's bill.

The Increase of Insanity.—London, says Dr. Robert Jones, is responsible for the production of over 70 insane persons a week. In 1859 there were in England 36,762 insane, or 1 to 536 of the population; there are today 113,964, or 1 to 293. The recovery rate from all cases of mania is also decreasing, being now 38.4%. Melancholia is increasing, and also premature dementia. The same complaint comes from the continent. Some statisticians contend that the increase is not real, but due to better census taking, segregation, and the great increase of the population, but there is a general conviction that the increase is altogether too definite to be explained in those ways. For the past six years the total increase of the insane in both public and private institutions of New York has averaged 708, but the increase up to October 1, 1903, was 941 over the previous year. The increase in the State hospitals, not including the two asylums for the criminal insane, was 918, as against 663, the average of the past six years. There are at present nearly 26,000 patients in the insane asylums of the State. Dr. White, of Washington, contends that there is more insanity in New England than elsewhere; and the amount decreases steadily as one goes from Boston west, or from Boston south. The statistics follow the figures being given in a sort of reverse form and representing the number of sane people, in each locality, for one insane:

New England	359
New York and Pennsylvania	424
Virginia, Maryland, Kentucky and Tennessee	610
Ohio, Indiana, Illinois and Michigan	610
The Middle West	750
The Southern States	935
Rocky Mountain States	1,263
Pacific Coast States	385

The explanation of the fact is found to be that the number of large cities—density of population—is greatest in New England, and decreases regularly in the same directions as insanity. The following figures, showing the density of population in the various parts of the country, correspond regularly with the proportion of insanity. The figures represent the number of inhabitants per square mile:

North Atlantic division	107.37
South Atlantic division	32.98
North Central division	29.68
South Central division	18.94
Western division	2.58

The conclusion is clear that in some way the increase of insanity is due to, or connected with city life. But that is too vague to satisfy the mind that seeks for real causes. Is it due to dissipation and vice? To poverty and overwork? To lack of sleep? To intellectual and educational strain? To the reckless fury of the desire for wealth and success? These appear to be the causes most commonly mentioned. Or can there be some overlooked factor which, beside all of these, or in all of them, is secretly at work?

Another iniquity of the Trades-Union spirit was the recent rule of the Chicago teamsters, who refused to allow milk to be brought into the city except once a day. One who knows that the freedom of milk from disease germs and its nutritional powers are entirely dependent upon its freshness, realizes what death-dealing this doubling of the time of kept milk brings to the children of the city. Apparently the teamsters prefer to kill their own children for the sake of the wage-scale. The *British Medical Journal* recently discussed a local epidemic of sore throat and fever traced to the use of the putrescent milk of four cows in the dairy of a farmer who, with others of his household, had suffered from "quinsy sore throat" about three weeks before the beginning of the local outbreak. Examination of the cows showed one or more teats of each animal inflamed and suppurating and the milk from these teats contained a large admixture of pus. The wives and mothers of the striking teamsters should get after them and teach them to value properly their own children. The great duty of women is child-raising and education. They are the housekeepers of the home, and properly, also, of the nation, and when they are once aroused to fulfil their office in a communal way there will be pure, fresh milk straight from the cow to the babies in the quickest time possible. Regard for health must govern all strikes.

An example of the noble work of preventive medicine is offered by the Commissioner of Health of Chicago, who says that of the city the aggregate ages of the 28,353 decedents of 1903—exclusive of the theater-fire victims, not yet reported to the department—was 910,982 years, or an average of 32.1 years each. In 1892 the total deaths were 27,754; aggregate ages, 612,588 years; average, 22.6 years each. In 1882, total deaths 13,696; aggregate ages, 264,998 years; average, 19.5 years each. In 1872, total deaths, 10,203; aggregate ages, 153,678 years; average, 15.2 years each. These figures show an increase in the average duration of human life in Chicago in less than a single generation—81 years—more than double in 1903 that of 1872. In 1903 the average age at death was 42% greater than in 1892; 60% greater than in 1882, and 111% greater than in 1872.

History of Circumcision.—The history of circumcision is one of the curiosities of ethnology and of antiquarian research. Till comparatively recent times, it was almost universally believed in western Europe that the origin of the operation as practised by primitive peoples originated with, and radiated from, the time and place of the Mosaic dispensation to the "chosen people." The scientific researches and the higher criticism of the past century have combined to explode that view. The researches of Welcke in this connection led, among other results, to the discovery of a true specimen of circumcision on the mummified person of Amen-en-hab, who lived between the years 1614 and 1555 B. C. The belief in the Jewish origin of the practice has, however, been even more hopelessly demolished by the discovery of the widespread practice of circumcision among the aborigines of the Australian continent and of the Malayan Archipelago. And at the present day circumcision pervades the troubled Balkan regions, and tra-

verses the whole extent of Asia Minor; crosses the Persian tableland, on which it has firmly fixed its hold; and still retains possession of a great portion of the vast peninsula of India. We have the evidence of Philostorgius that it prevailed among the Arabs as early at least as 342 B. C. The practice is so nearly universal among the primitive tribes of Central Africa that it has been truly remarked that it would be far easier to enumerate the tribes who do not use circumcision than those who do. And its extraordinary prevalence over the greater part of the Dark Continent is further illustrated by the fact that it is used by the Abyssinian Christians as well as by the Bogos and the Copts. And dear to the heart of the antiquarian and of the ethnologist is the fact that the aboriginal Australian was found to circumcise his male child with a sharp stone—as did Zipporah, the wife of Moses, even before the children of Israel were led up out of the land of Egypt! While to crown the obstruction to the acceptance of the older notion of an exclusively Jewish origin, latter-day researches have proved the existence of the practice of circumcision among some native American Indians, even preserved to the present day.

Ritual Practice of Circumcision: Its Dangers.—The hygienic and operative importance of the ritual practice of circumcision has recently attracted a good deal of attention and discussion both within and without the Jewish community. This is due to the fact that two deaths of Jewish infants were reported, which occurred under circumstances that left no room for possible doubt of their being in each case the direct result of the operation. Whether it was that the occurrence of such accidents were hushed up it is difficult, or rather impossible, to decide; but deaths from such causes had been so seldom heard of till within the last few years that many Jews believed that a fatal case never occurred as a consequence of this, the oldest as well as the most sacred of all surgical procedures. Of course, every cutting operation endangers life when the individual happens to be the subject of hemophilia. And the possible occurrence of sepsis must be considered as in all other operations, although the chances are less than in most others.

But even when the infant is not a "bleeder," copious hemorrhage is one of the things to be dreaded, on account of the fact that children do not bear the loss of blood so well as grown-up individuals. For this reason, some Jewish surgeons who have discussed the question recently, still recommend the old tearing method of carrying out the second stage (*peri'ah*) of the ritual circumcision, by which the lining membrane of the prepuce is divided along the dorsum of the glans, after the conclusion of the first stage (*milah*), which consists of the removal of the cutaneous flap of foreskin. Such tearing, according to the familiar manner of lacerated wounds, is almost free from hemorrhagic sequels in all cases; and this advantage is held by some good judges to compensate for the greater danger of sepsis—the tearing being always carried out by the Jewish operator by seizing each lateral segment between the thumbnail and index finger, and then using forcible divulsion. The third (and final) stage of the Jewish ritual operation consists in the sucking of the wound (*mezizah*) by the operator. The latter (*mohel*), before applying his lips, takes some wine in his mouth, and then sucks the wound vigorously, after which he expels the mixture of wine and blood into a special receptacle, which is always placed in readiness for the purpose. This proceeding is repeated several times, and completes the

operation, excepting the control of troublesome bleeding and the dressing of the wound. For the former purpose, various astringent applications are used in different parts of the wound. They are usually applied by moistening or powdering, as the case may be, small circular pieces of linen, each of which has a central orifice through which the glands is drawn. They are closely applied to the cut surface, secured by a few turns of a small bandage, and usually allowed to remain in place till the third day. They are kept covered by a diaper, and the wound is usually found to have almost or quite healed on their removal. The mohel usually remains for an hour or so with the child, lest any traces of recurring hemorrhage should arise.

Considerable opposition to the continuance of the practice of meizah has arisen of recent years, on account of its nonconformity with the principles of asepsis in the treatment of wounds. Also on account of a sensational case which occurred in Cracow of a mohel who in this way inoculated a number of infants with syphilis, his mouth having been the seat of specific ulceration.

The Opticians' "Optometry" Should be Made Illegal Instead of Being Legalized.—The "Optical Society of the State of New York" has prepared a bill which it is seeking to have made law and it is actually asking physicians for their help in securing its passage. The first section of this bill is a definition of "optometry," which reads as follows:

The employment of any means, other than the use of drugs, for the measurement of the powers of vision, and the adaptation of lenses for the aid thereof.

Section 9 of this proposed bill makes a distinction between optometrists and "those who sell spectacles or eyeglasses on prescription from any duly qualified optometrist or physician," from which we learn much! In the letter seeking the aid of physicians there are these paragraphs:

As the measure does not invade the domain of medicine, we desire the support of all medical practitioners, believing that the compulsory education of those engaged in fitting spectacles and eyeglasses will prove a pronounced public service. . . . We want all who practise optometry to be able to recognize disease for the sole purpose of urging the importance of consulting qualified physicians.

This is the rankest hypocrisy and deceit. "Optometry" practised by any but physicians should be made illegal instead of cunningly legalized. No "optometrist" can possibly "recognize disease" except after a medical education. It is as important that the treatment of diseases of the eye should be solely in the hands of medical men as that druggists should be disqualified from prescribing for other diseases. Moreover there is a double deceit in all this, for almost no spectacles or eyeglasses are prescribed by the medical man for the sole purpose of "aiding vision." Myopia is a disease itself, and astigmatism and farsightedness, if not always of themselves diseases, do produce many and profound diseases, directly and inevitably. There are no instruments of the *materia medica* more powerful for good or evil than lenses used in spectacles. The eye is the most valuable of the sense organs of the body; and its diseases and the function of vision are indissolubly bound together. The disorders of vision cannot be treated apart from the diseases of the eye, and also from the diseases of the brain and of the whole body which result from optometry good or bad, or from the want of it. Every physician should labor to make optometry illegal by any other than the physician.

BOOK REVIEWS

Functional Diagnosis of Kidney Diseases, with Especial Reference to Renal Surgery.—By LEOPOLD CASPAR and PAUL FRIEDERICH RICHTER. Translated from the German by ROBERT C. BRYAN and HENRY L. SANFORD. P. Blakiston's Son & Co., Philadelphia.

This is a small volume of over 200 pages in which the authors discuss the various surgical affections of the kidney, together with their clinical aspect. They recite, in some detail, a number of cases occurring in hospital practice as illustrative of the matter under discussion. The latest investigations concerning renal sufficiency or insufficiency; ureteral catheterization; cryoscopy; the quantitative estimation of single chemic elements, especially nitrogen; the phloridzin test, etc., are taken up and discussed at length. The volume contains many valuable suggestions concerning the latest methods and investigated kidney diseases.

Elements of Surgical Diagnosis.—By A. PEARCE GOULD. Third edition, revised and enlarged. W. T. Keener & Co., Chicago.

This little volume of some 600 pages needs no introduction to the profession. Sufficient to say that the third edition has appeared, in which the whole text has been revised; much has been rewritten, and many additions have been made. A section on the diagnosis of the intracranial complications of middle-ear disease has been added, and chapters on the diagnosis of abdominal tumors, and of certain acute abdominal diseases have been introduced. The general plan and scope of the work remains unaltered, and its brevity, terseness, and recitation of the essentials in surgical diagnosis are important factors worthy of comment. All the important surgical affections are taken up, the symptoms given, and the treatment indicated. The new edition will be well received.

Infectious Diseases.—By G. H. ROGER. Translated from the French by M. S. GARRIEL. Lea Brothers & Co., New York and Philadelphia.

This book contains about 900 pages devoted to a scientific discussion of infectious diseases, their etiology, pathology, and treatment. Special attention is directed to the author's consideration of the influence of infection upon the various organisms of the body. His research in experimental appendicitis, pseudotuberculosis, variola, and the vesicatory diseases are particularly interesting and noteworthy, as are also his treatment of the pathology of fevers and the defense of the organisms against infection. The final chapters, comprising about one-fourth of the volume, are devoted to a discussion of the therapeutics of infectious diseases. This is a feature which will be much appreciated by practitioners, and will add to the value and popularity of the work. The author's reasoning and deductions concerning infectious diseases, suppuration, gangrene, septicemias and pyemias, nodular infections, cellular degenerations, etc., are philosophic and classic. We predict for the work a hearty reception from the profession.

Operative Surgery.—By WARREN STONE BICKHAM. W. B. Saunders & Co. Philadelphia, New York and London.

This is a volume of almost 1,000 pages devoted to the surgical anatomy and surgical technique which applies to all the important surgical affections of the human body. It is arranged systematically, tersely expressed and well written. It contains many splendid illustrations illustrative of surgical procedures. It is thoroughly up-to-date and modern in every respect. For ready reference on any surgical subject it will prove of great value to the surgeon. It is practical and deals with all surgical procedures in a simple, direct, concise and thorough manner.

Surgery: Its Theory and Practice.—By WILLIAM JOHNSON WALSHAM. Eighth edition by WALTER GEORGE SPENCER. P. Blakiston's Son & Co., Philadelphia.

This is a volume of some 1,200 pages devoted to the whole subject of surgery. The fact that more than 38,000 copies of this work have heretofore been published is sufficient guarantee of its appreciation by the profession. The new edition is enlarged,

many new illustrations have been added and the work brought thoroughly up-to-date. More than the usual space is devoted to infective processes, tumors and cysts. The author has not followed the usual custom of entirely omitting the various specialties correlated to surgery, such as laryngology, otology, gynecology, etc., but has included sections dealing with the surgical aspect of these various affections. The work is well written, contains many valuable illustrations, and covers the whole subject of surgery.

A Manual of Operative Surgery.—By Sir FREDERICK TREVES. New edition. Revised by the author and Jonathan Hutchinson, Jr. In 2 volumes. Volume I published by Lea Brothers & Co., Philadelphia and New York.

Since the first edition of this work in 1891, it has been much appreciated by the profession. The new edition is revised, enlarged, and presented in 2 volumes. The volume under consideration is devoted to general principles, ligation of arteries, operation upon nerves, amputation, operation upon the bones and joints, and tenotomy. The author describes in detail the various operations included under the several headings enumerated, and gives specific directions as to proper surgical procedures in each instance. The work meets every expectation that would be entertained in a volume coming from the hands of a man so prominent in the profession. It is well written, forcible, particular in details, and sufficiently exhaustive without being cumbersome and laborious. Its numerous illustrations add materially to the elucidation of the subject matter. It should be in the library of every surgeon.

Clinical Discussions on Minor Surgery.—By JAMES G. MUMFORD. Published by the Old Corner Book Store, Boston.

This is an interesting handbook of something more than 100 pages, consisting of clinical talks on what is ordinarily denominated minor surgery. The subject matter is embraced in 10 lectures under the following headings: The examination and study of cases; incised wounds; simple fractures; lacerated wounds; compound fractures; granulating wounds and varicose ulcers; felon, whitlow, paronychia, and palmar abscess; boils and carbuncles; bunions, ingrowing nails, corns, and warts; and massage. The writer's experience as a clinician and teacher has enabled him to place before his hearers and readers the main points in the successful treatment of the subjects under consideration. While, of course, the work covers a very limited field, it is essentially practical and common sense in that part to which it is devoted.

Nurse's Guide to Surgical Bandaging and Dressings.—By WM. JOHNSON SMITH, F.R.C.S. Philadelphia: J. B. Lippincott Company.

This little book contains 162 diminutive pages filled with elementary instructions regarding antiseptic and aseptic surgery, the modern treatment of wounds application of bandages, etc. There are 70 illustrations. It forms a handy pocket reference book for nurses in surgical wards that should prove of distinct value.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Nineteenth Annual Report of the Bureau of Animal Industry: For the year 1902. Government Printing Office, Washington, D. C., 1903.

Transactions of the National Association of United States Pension Examining Surgeons: Vol. I, 1903. Published by the Association, Rochester, N. Y., 1903.

Electro-Diagnosis: Scheme for the Differential Testing of Nerves and Muscles.—By J. MONTGOMERY MOSHER, A. M., M.D., Clinical Professor of Insanity, Neurology, and Electrotherapeutics, Albany Medical College; Attending Specialist in Mental Diseases, and Physician to the Outpatient Department for Nervous and Mental Diseases, Albany Hospital. Illustrated. Brandow Printing Company, Fort Orange, Press, Albany, N. Y., 1903. Price, \$1.00, net.

Diseases of Women.—By GUSTAVUS M. BLECH, M.D., Professor of Operative Surgery, Jenner Medical College, Surgeon-in-chief and Attending Gynecist Moimonides Polyclinic, etc. M. Robertson & Co., Chicago, 1903.

AMERICAN NEWS AND NOTES.

GENERAL.

A Wise and Practical Frenchman.—A French automobilist proposes that all motorists carry a compact pharmaceutical and surgical outfit for the purpose of rendering "first aid to the injured." This, in view of the fact that accidents usually occur on open roads, distant from cities and villages where medical attendance can be had, seems to be an excellent suggestion.

Miscellaneous.—AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY: The annual meeting will be held at Fall River, Mass., January 30. PROFESSOR W. S. HALSTED, of John Hopkins University, Baltimore, has been tendered the invitation to deliver the Cavendish lecture before the West London (Eng.) Medico-Chirurgical Society, at its annual meeting at Hammersmith, Eng., in June.

Professional Manufacture of Diphtheria Antitoxin.—Several cities, especially the largest ones, have rendered any monopoly in the manufacture of this antitoxin an impossibility by making and selling it through the local Boards of Health. Physicians are given the preparation for use among the poor. In Philadelphia a somewhat novel method of carrying on the manufacture of the city's antitoxin has been devised. The horses are those used by the mounted police. They are first given a good rest and fattened up, and the care, etc., during the inoculation period leaves them in excellent condition for subsequent police service. There is said to be a saving of about 60% to the city by this method.

An Admirable Suggestion.—It is not generally known that the work of Dr. Robert Fletcher, the editor of the lately revived *Index Medicus*, is entirely a work of love, and has been for many years. Dr. Fletcher has not received one dollar of compensation for all his editorial work, which involves the personal reading of the proof 3 times over, a labor which only those who have dealt with the unusual foreign languages represented in the *Index Medicus* can appreciate. A number of his friends and admirers have combined to have his portrait presented to the library of the Surgeon-General's office where, in the scene of his labors, it will always remind later generations of his splendid work. A committee has been appointed, which is doing active work to secure funds for this purpose. The fund is not yet complete, and any who feel disposed may contribute thereto.

Physician May Charge Maximum or Minimum Fees.—In rendering judgment concerning a point in litigation between a Philadelphia physician, claiming the right to charge a fee in accordance with the patient's financial standing, on one hand, and a belligerent patient on the other, Judge Ashman, of the Orphan's Court, said: "In my opinion, a physician may fairly demand, as the exceptant admitted was his practice, a maximum and a minimum rate of pay, just as the circumstances of his patients shall seem to indicate will be proper. It is true that a physician is unlike a tradesman, who has different qualities and therefore at varying prices; he is bound in every case to give his best service. But it does not follow that this service is worth the same in every case. Where it saves a human life its value is unestimable, for it is as true as in the days of Job that a man will give all that he has for his life. With somewhat of unanimity the rhetoricians from Socrates to Ingersoll, have agreed with the inspired patriarch that human life, whether of high or low degrees, is equally sacred, and every sane man and every court in Christendom admits the truth of the proposition. No flight of rhetoric, however, can escape the plain fact that life has a pecuniary value of variable quantity, greater, for instance, in the case of the millionaire than in that of the laborer. The question before us is one of values, and the law which must govern it is a thing of common sense rather than of sentiment. The practitioner who boasts that his terms are one and invariable must choose between the 2 rates; if he adopts the lower one he will probably starve; if he selects the higher one he will be compelled very often to make large reductions at the risk of wounding the self-respect of his poorer patients. The moral distinction between the code of the doctor who in theory has but 1 charge, and in practice 2, and his ruder but more candid brother who declares at the outset that he has a maximum and a minimum charge, fades away on the slightest analysis into a play upon words."

EASTERN STATES.

The Control of Tuberculosis.—The *New York Times* of January 7, commenting upon this subject editorially, quotes Dr. W. Gilman Thompson with the following statement: "Within the past decade, in the State of Massachusetts alone the mortality from tuberculosis has been reduced exactly one-half." It then says: "In view of the fact that between 1890 and 1900, the population of Massachusetts increased from 2,093,889

to 2,855,346, a net gain of 791,457, this statement was so startling as to demand verification. This we have been at pains to make and the official facts are as interesting as the generalization to which they relate. Between 1885 and 1902, notwithstanding the increase of population above noted, the number of deaths from tuberculosis in Massachusetts shows a decline from 5,955 to 4,685. During the period of 50 years since 1853 the deathrate per 10,000 inhabitants of that State has declined from 42.7 to 15.9. This is full of encouragement, and shows without argument the value of State medicine intelligently directed. Its (Massachusetts) deathrate from tuberculosis during 10 years, per 10,000 of population, has been as follows:

Years.	Deathrates from Tuberculosis.
1893.....	23.1
1894.....	2.23
1895.....	21.9
1896.....	21.7
1897.....	20.8
1898.....	19.7
1899.....	19.0
1900.....	18.5
1901.....	17.5
1902.....	15.9

The "white plague" is obviously controllable, and its extinction will be a beneficent achievement of medical science.

NEW YORK.

A Useful Official Retained.—President Darlington of the Board of Health, has announced the appointment by the Board of Dr. Ernest J. Lederle, former Health Commissioner, as Consulting Sanitarian of the Board of Health. The position is honorary, there being no salary.

The New York Women's Infirmary Fifty Years Old.—The fiftieth anniversary of the founding of the New York Infirmary for Women and Children was held at the Waldorf-Astoria, January 16. Addresses were made by Dr. William Welch, Dr. Emily Blackwell, Dr. Annie S. Daniel, Miss M. Carey Thomas, and others.

Active Measures to Prevent Smallpox.—News from Lockport, N. Y., under date of January 12, says: The Board of Health has ordered all local theaters, amusement halls, dance halls, and other public meeting places closed and the public library to cease issuing books, in order to guard against any epidemic of smallpox or other contagious diseases prevalent in Niagara and adjoining counties.

Mortality in New York City.—For the week ended January 9 there were 364 deaths in Greater New York from pneumonia, 143 more than from the same cause for the corresponding week last year. Altogether there were 1,635 deaths recorded last week, as against 1,320 for the corresponding week in 1903, and of all the diseases which were responsible for the large total last week, pneumonia had by far the largest number of victims.

Pneumonia and Other Diseases in New York.—Following the bitter cold weather of the early part of last week there were 364 deaths from pneumonia in the 5 boroughs of the city. The hospitals are crowded with pneumonia patients, and grip is also prevalent. The deathrate for New York City for the week ended January 9 was 22.23, and for the same week last year, 18.45. Last week's record is the worst since March, 1900, and during the corresponding week last year there were only 22 deaths from pneumonia. The Health Board, alarmed at these figures, is preparing to battle with the disease. As a precaution against the spread of pneumonia, the antisputting law will be vigorously enforced. An investigation will also be made of the temperature of the cars on the surface and elevated roads.

PHILADELPHIA, PENNSYLVANIA, ETC.

The Medical Club of Philadelphia.—Nearly 300 physicians of Philadelphia were present at the quarterly meeting of the Medical Club at the Hotel Bellevue January 15. Officers were elected for the year 1904, Dr. E. E. Montgomery being elected president.

In Memory of Dr. Morton.—An oil painting of the late Dr. Thomas George Morton was presented to the Pennsylvania Hospital by the Association of Resident Physicians of that institution, to commemorate the long connection of Dr. Morton with the hospital and his services as a surgeon and physician.

Assign Cause for Pneumonia in Philadelphia.—The crowded and unheated condition of the trolley cars, the smoke nuisance, slush in the streets, and the inclement weather have caused the epidemic of pneumonia which now prevails in the city of Philadelphia, according to opinions expressed by physicians.

Must be Vaccinated.—During the week just ended a list has been made of all the men in the University of Pennsylvania who have not been vaccinated, and they will be shut out from classes and the dormitories until the regulations shall have been complied with. The same orders also apply to the faculty and the University employees.

\$500,000 for a Hospital.—The estate of Henry B. Ashmead, valued at \$500,000, according to the terms of his will, probated recently, reverts to the Episcopal Hospital as a memorial to his wife after the death of his widow and daughter. Mr. Ashmead, who was a prominent printer, died recently at his home in Philadelphia.

Mortality in Philadelphia.—Deaths from all causes last week numbered 736, the highest deathrate in any 7 days for 3 years. Of this number 26% were the result of throat and lung diseases. Heart and kidney diseases caused 14% and pulmonary tuberculosis 9%. There were 9 deaths from grip. New cases of contagious diseases were 102 less than for the previous week.

Municipal Hospital to be Destroyed by Fire.—It has been suggested from influential sources that the old Municipal Hospital of Philadelphia, when abandoned for the new institution, shall be completely destroyed by fire as the best means of preventing future epidemics of contagious diseases in the vicinity of the old institution. It is likewise advocated that the construction of new buildings shall be such that after a term of years they too can be destroyed by fire.

Smallpox near Delaware City.—It is reported that smallpox is epidemic among the boys of St. James' Rectory, a Roman Catholic institution near Delaware City. A few weeks ago one of the sisters of charity at the rectory was stricken with the disease and was removed to the emergency hospital at Farnhurst. Recently it was discovered that 5 of the inmates had contracted the disease, and they were removed to the isolation hospital. A careful watch is being kept over the other boys at the home.

Improvement at the Polyclinic Hospital.—New buildings and improvements have lately been added to the Polyclinic Hospital at a cost of \$108,965.07. New equipment for the nurses' home, new private rooms, cost \$3,347.42 additional. The maintenance cost of the institution for the year has been \$63,331.78. Total income and receipts, \$56,255.93, leaving a deficit of \$7,075.85. Unpaid building contracts, amounting to \$44,005.95, are still outstanding. Applicable to this purpose, the institution is shortly to receive legacies amounting to \$13,500, which leaves \$30,505.95 still to be provided for. The total outstanding indebtedness of the institution on December 31, was \$101,304.54.

Councils Ask for Warm Cars.—A resolution has been introduced in the City Councils of Philadelphia, which reads as follows:

WHEREAS, The unheated condition of the trolley cars in this city has endangered the health of the people, and has gone far to render of no avail the valuable services of Dr. Edward Martin, Director of Public Health, in promoting the well-being of this community; and,

WHEREAS, Street cars in New York and other large cities of the country are heated in winter time; now be it

Resolved, By the Select and Common Councils of the city of Philadelphia, that the Philadelphia Rapid Transit Company is hereby respectfully requested to provide for the heating of all street cars during winter weather, so that it will be impossible for the temperature of any car to sink below 32° F.

No Scarcity of Antitoxin in Philadelphia.—The report that because of a monopoly in diphtheria antitoxin the city of Chicago is not able to buy any, Dr. A. C. Cairns, of the Health Department, said it does not affect Philadelphia, because nearly all of the antitoxin used here is made by the city. The horses of the Police and Fire Bureaus are the subjects used to create it. The antitoxin is furnished free at the Bureau of Health to all physicians who apply for it. The application must be made in writing on a blank that requires the physician's as well as the patient's name and address, together with a history of the case. The city saves \$5,000 a month by preparing its own antitoxin. The preparation is put up in 1 ounce bottles, and the same quality would cost \$2.50 at a drug store. The city saves about 60% by making instead of buying the antitoxin.

Phipps Institute will Make an Exhibit.—Physicians of the Phipps Institute and the managers of the White Haven Sanitarium will take part in the American crusade against tuberculosis by making an exhibit at the Maryland Tuberculosis Exposition. The exposition is to be held in Baltimore, commencing January 25. Dr. Lawrence Flick, who is at the head of the Phipps Institute and the White Haven Sanitarium, will deliver an address on January 28. These institutions propose to show in a graphic way the results of their investigations. This is in keeping with the general plan of the exposition, which is attracting the attention of the tuberculosis experts in all parts of the world. The Phipps Institute will have an exhibit of those materials used to prevent tuberculosis. Among these will be paper napkins, which all infected persons are taught to use; paper bags in which the napkins must be placed preparatory to burning them, and sputum cups. The display from the sanitarium, which is situated on a mountain side at White Haven, Pa., will be the more interesting. It will consist of photographs of the patients in the open air, where they are compelled to spend most of their time, summer and winter, and will show them in the various stages of the cure.

SOUTHERN STATES.

Cocain Habit in Washington.—In his annual report to the District Commissioners, Major Sylvester declares the drug habit within his jurisdiction to be vastly on the increase. "While there has been no general increase in the opium habit," he says, "that of cocain has taken a firm hold on the lower classes. It is bound to become a destructive agency unless something is done to prevent its sale by druggists. Two years ago the drug was hardly known, but the habit has grown, and the wreck of lives which accompanies the use of this deadly drug and its sister drugs, morphin, chloral, and other pharmaceutical preparations, and even patent medicines, is becoming apparent. The police are powerless to raid the opium joints save on the charge of disorderly conduct, and the fine for this misdemeanor is inadequate to check the scourge." He urges the necessity for the prohibition of the sale of these drugs save upon the prescription of a physician.—[*Washington Times.*]

WESTERN STATES.

The Medical Fortnightly.—The first number for the year 1904 of this biweekly magazine appears in an altogether new form and dress, which adds very materially to its appearance.

Indiana Medical Journal.—A portion of the leading editorial in the January number of this journal says: With the present issue, the *Journal* drops its modest Quaker gray and robes itself in the white ermine characteristic of its elements of justice and purity. A heavier paper has been selected, the size increased and arrangements made for better and more abundant illustrations.

Mortality of Michigan during December, 1903.—There were 2,942 deaths returned to the Department of State for the month of December, or 319 more than reported for the previous month. The deathrate was 14.1 per 1,000 population, as compared with 12.9 for November. There were 490 deaths of infants under 1 year, 191 deaths of children aged 1 to 4 years, and 944 deaths of elderly persons over 65 years of age. Important causes of death were as follows: Tuberculosis of the lungs, 158; other forms of tuberculosis, 33; typhoid fever, 48; diphtheria and croup, 96; scarlet fever, 17; measles, 16; whooping-cough, 23; pneumonia, 376; influenza, 49; cancer, 151; accidents and violence, 182. There was a decrease in the number of deaths reported from typhoid fever, and the usual seasonal increase in deaths reported from pneumonia and influenza. There were no deaths from smallpox during the month. One death from chickenpox was reported from Highland township, Osceola county.

To Combat the Antitoxin Trust.—An exchange says the Chicago Medical Society and the Illinois State Medical Association are expected to begin legal proceedings against the Antitoxin Trust under the antitrust law. An official statement regarding the trust in antitoxin has been issued by Secretary Pritchard, of the Health Department. The statement says: "The Antitoxin Trust is nothing more nor less than a traffic in human life. Three concerns, which manufacture and practically control the antitoxin supply of almost the entire country, have seen fit, arbitrarily, to advance the price of their product 100%. This discovery was made by the Department of Health of the city of Chicago when, in ordering its needed supplies for charity work, it was met with the increased quotations. The department felt compelled to call public attention to the evidence that a combine had been formed which effectually controlled the price of the only known remedy for the most dreaded scourge to the child life of the country. The horizontal increase in the price made by the trust means that the city of Chicago will be compelled to appropriate double the sum to do the same amount of charity work in diphtheria cases for 1904 that it did in 1903. But it must be remembered that this burden will fall heaviest on the self-respecting, self-supporting heads of families of modest incomes. To all such, should diphtheria invade their homes and they be compelled to pay the increased prices, the burden put upon them by the Antitoxin Trust will indeed be grievous. This applies not only to Chicago, but practically to the entire country."

CANADA.

Healthful Conditions in Winnipeg.—Dr. A. J. Douglas, city medical inspector, has reported his work for the year 1903 to the civic health committee. During the 12 months he attended 1,490 cases and vaccinated 781 people. In 1902 he attended 1,342 patients and vaccinated 3,330. The difference in the number of vaccinations for the 2 years is caused by the action of the public school board which in 1902 made vaccination compulsory, and excluded unvaccinated children from the public schools. During the past 2 years smallpox cases have been very infrequent, while cases originating in the city were a rarity. Disease has been rampant only on a few occasions, when it was not serious. Of epidemics there have been none, and taking the public health as a whole it has been about average, and compares favorably with that of any other city.

FOREIGN NEWS AND NOTES

GENERAL.

Honor Robert Koch.—The sixtieth birthday of Dr. Robert Koch was celebrated on December 11. A portrait bust was unveiled in the Institute for Infectious Diseases, Berlin, a museum for bacteriology was established and a "Festschrift" is in press. Dr. Koch expects to return from South Africa in March.

Well-merited Prize.—Professor Karl Schleich, of Berlin, has received from the University of Würzburg a medal and a 1,000-mark prize for the discovery of a method of making surgical operations painless by what he calls the "Infiltrationsanästhesie." This is the wellknown "Schleich's fluid," used for the purpose of producing local anesthesia.

Rats and Bubonic Plague.—News from Hamburg under date of December 30, says the inquiry into the mortality among rats on the German steamer Cordoba, from Santos, Brazil, November 25, via Bahia, December 2, confirms the report that they died of bubonic plague. The vessel has been towed to Strandhafen and quarantined. There is no sickness among the crew, and it is officially announced that the precautions taken preclude the possibility of public danger.

The Health of London.—The report of the health officer for the county of London for 1902 has just been issued. It shows that London is one of the healthiest of the great cities of the world. The deathrate from all causes in 1902 was 17.2 per 1,000 persons, compared with a rate in St. Petersburg of 23, Rome 21.9, Vienna 19.4, New York 18.7, and Paris 18.4. Berlin is superior, with 16.1. But while the deathrate has steadily decreased, the birthrate fell also. The births numbered 132,810, or 22.5 per 1,000, the lowest recorded since the institution of civil registration. In the period between 1861 and 1890 the rate was 35.4, between 1881 and 1890 it was 33.2, and between 1891 and 1900, 30.3. The marriages show a slight increase.

Mission Hospital in Turkey.—Central Turkey is the subject of an article by Dr. F. D. Shepard, in the *Missionary Herald* for January, in which he says: Our hospital at Aintab is the only one in an area twice as large as New England, and we draw patients from all that area and occasionally from beyond. The German Mission in Oorfa has a missionary physician and a dispensary. Aleppo has an English medical missionary and dispensary and some well-qualified native physicians. Thirty-two beds in the hospital at Aintab will accommodate only half our surgical cases. Taking all the departments of the work together we find that we have had during the year a grand total of 38,801 calls upon our attention, not including the work of dispensers in putting up prescriptions. Our present hospital building is wholly inadequate to this great amount of work.

From Professor Robert Koch.—An exchange states that Professor Robert Koch, the German scientist, has written from South Africa a letter to a member of the Committee on the Prevention of Tuberculosis of the New York Charity Organization Society, expressing great satisfaction that at last some one has arisen to interfere with the swindlers who have been trading upon his name and reputation. He says: "For my part, whenever opportunity offered itself, I have never neglected to declare that I had nothing whatever to do with Koch Lung Cure, and that these concerns used my name for fraudulent purposes. I would long since have brought suit against these swindlers, but friends familiar with the conditions in America advised against it, saying that according to the law in the United States these impostors could not be prosecuted. I, too, begin to believe that the only rational way to deal with them is the one taken by your Committee on the Prevention of Tuberculosis. The public should be informed through the press of the outrageous manner in which these unscrupulous people cheat and fleece the unfortunate tuberculous."

Babes Killed by Ignorance.—An exchange says: The French, and the Parisians in particular, are becoming alive to the urgent necessity of arresting the destruction of infant life. A hundred and fifty thousand infants of the age of 12 months or under die every year in France—a high proportion in a population of about 38,000,000. The statisticians, including the chiefs of the medical profession, hold that the lives of at least 100,000 of these infants can be saved. Myriads of babies die because their mothers—belonging principally to the working class—do not know how to take care of them, or because poverty prevents them from taking sufficient rest before and after birth. As a remedy for this last evil the Senate has just given its approval to a proposal prohibiting the employment of laboring women during the 2 weeks preceding and the 4 weeks following the birth. The prefect of the Seine has just inaugurated in every one of the 20 arrondissements of Paris a permanent system of conferences in maternity for the instruction of women of the working classes, or of any others in need of enlightenment. These conferences are to be held at the headquarters of every municipal division of the capital. They will be presided over by the local mayors and by the leading scientific men of Paris.

Deathrate in French Army.—During the recent debate on army estimates in the French Chamber of Deputies some interesting but somewhat alarming statistics relating to the health of the troops were given. It appears that last year 50,000 cases of sickness were treated in the different barracks, and 125,000 more at hospitals. There were 3,500 deaths, and more than 19,000 men were discharged from the army unfit for military service. Most of the trouble can probably be traced to the bad condition of the soldiers' quarters, many of which are undoubtedly contaminated. Typhoid fever and tuberculosis are spreading to an alarming extent. Comparatively few barracks are so constructed as to provide a proper allowance of air to the soldiers, and in some dormitories the beds actually touch each other. There seems to be an inadequate medical service, there being but 1,500 doctors in the French army, while that of Germany has 3,000.

OBITUARIES.

Pulaski F. Hyatt, at his home in Jersey Shore, Pa., January 17, aged 67; a graduate of the medical department of the University of Georgetown, Washington, D. C. in 1875. He was surgeon to the Carver Hospital, Washington, D. C., during the Civil war; in 1876 he was sent to Florida as the personal representative of Samuel J. Tilden, to superintend the counting of votes in that State. In 1891 he was appointed trustee of Danville Hospital, and in 1893 he was appointed by President Cleveland, U. S. Consul to Santiago de Cuba, which position he retained until the outbreak of the Spanish-American war.

William H. Ireland, at his home in Camden, N. J., January 18, aged 60. He was one of the oldest practitioners of Camden, and served as county physician for three years; a graduate of the University of Pennsylvania, in 1867. He had been president of the county and city Medical Societies, and was a permanent or life delegate to the State Medical Society from the county society.

John Kost, formerly a professor in Adrian College, and at one time chancellor of Heidelberg University, died January 11 at his home in Adrian, Mich. He was 86 years of age. His writings and original researches had brought him prominence in international scientific classes. He had lived in Adrian for 40 years.

Fred. W. Keehl, at his home in Waterloo, Iowa, January 1, from typhoid fever; a graduate of the University of Iowa, in 1897; a member of the county, district, and State Medical Societies, and of the American Medical Association.

William H. Bryant, at his home in Savannah, Mo., December 24, aged 71; a graduate of the Kentucky School of Medicine, Louisville, in 1858; a member of the Missouri State Examining Board for many years.

Charles Merrill Clark, at his home in Chicago, December 28, aged 69; a graduate of the medical department of the University of New York in 1857; surgeon of the Federal Army during the Civil war.

Henry L. Tolman, who had a national reputation as a microscopist, January 14, aged 55. He was a member of the faculty of the Chicago College of Physicians and Surgeons.

John Scott Hughson, at his home in Sumter, S. C., December 29, aged 63; a graduate of the Medical College, of the State of South Carolina in 1867; one time mayor of Sumter.

Frederick W. Vandersloot, at his home in York, Pa., January 18, aged 70; a graduate of the medical department of the University of Maryland, in 1855.

Theo. F. Sterling, at his home in Petersburg, W. Va., December 29. He was surgeon to the First Virginia Volunteer Infantry during the Civil war.

Richard F. Scruggs, at his home in Sweetwater, Tenn., December 28, aged 70; a graduate of the Jefferson Medical College, Philadelphia, in 1859.

Daniel Devine Cunningham, at his home in Cold Water, Mich., January 4, aged 41; a graduate of the University of Michigan in 1892.

E. J. Stille, at his home in Hope Church, Pa., January 3; a graduate of the Western Pennsylvania Medical College, Pittsburgh, in 1889.

Robert McIntyre, at his home in Cobourg, January 4, aged 66; a graduate of the University of Victoria College, Cobourg, Ontario.

Henry C. Ahlborn, at his home in Boston, January 9; a graduate of the New York Homeopathic Medical College and Hospital.

S. Foster Quimby, at his home in Salem, Mass., December 23, aged 68; a graduate of Harvard University Medical School in 1864.

P. H. Woolsey, one of the best known physicians in Orange, Sullivan and Delaware counties, New York, January 12, aged 80.

J. Fenton Underwood, at his home in Penn Yan, N. Y., December 20, aged 49; a graduate of the University of Vermont in 1896.

Daniel Voorhees Scott, at his home in Jeffersonville, Ind., January 6, aged 32; a graduate of the University of Louisville in 1894.

T. Erskine Todd, at his home in Laurens, S. C., December 25, aged 49; a graduate of Jefferson Medical College in 1874.

Philip H. Greir, at his home in Trenton, January 2, aged 74; a graduate of the University of Pennsylvania.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

A CRITICISM OF MOOR'S CLAIMS FOR "UREINE" AND HIS METHOD FOR THE QUANTITATIVE DETERMINATION OF UREA.

BY

WILLIAM J. GIES, M.S., PH.D.,

of New York.

Adjunct Professor of Physiologic Chemistry at Columbia University, and Consulting Chemist at the New York Botanical Garden.

It is now nearly 4 years since Dr. William Ovid Moor first announced to the Thirteenth International Medical Congress, convened in Paris, "the discovery of ureine, the principal organic constituent of urine, and the true cause of uremia."¹

In his earlier papers, Dr. Moor stated that "ureine is the most characteristic component part of urine," that it existed in "a quantity superior to urea," that it "belongs to the group of alcohols of the aromatic series," and "at a temperature of about 80° C. begins to split into several bodies belonging to the class of oxyacids;" that "it is a ferment with a potential energy of at least 130° C.," and "is the principal cause of the ammoniacal fermentation of urine, for without its presence urea cannot be decomposed into ammonia and carbon dioxide;" that "none of the known organic or inorganic components of urine," except ureine, "could account for the intense blue reaction given by the human urine with potassium ferrieyanid and ferric chlorid;" that "it is this constituent (ureine) of urine which is the cause of its specific odor;" that "it is the true cause of uremia," etc.

A careful examination of Moor's papers on the subject of ureine failed to reveal any substantial chemie evidence of the truth of any of the foregoing claims. There were, however, so many striking indications in them of chemie crudity in the manipulations leading to the separation of "this wonderful organic fluid," this "mysterious chemie body," as Moor termed it, that I found it impossible to accept *any* of Moor's special conclusions, least of all the absurd deduction, based apparently on nothing but imagination, that "without ureine all organic matter would become converted into urea, which would remain in nature without any use, and thus within a limited period of time all vegetation, and animal, as well as human, life would cease."

That the discovery of such a remarkable substance would be an event of world-wide interest and importance goes without saying, and in order to ascertain how large might be the kernel of truth in what seemed to be a preposterous jumble of psychology, chemistry, and biology, we made in our laboratory a careful study of the methods used by Moor and the products obtained with them.

This study² demonstrated conclusively that "ureine is not a chemie individual, but a mixture containing several of the organic substances³ and a considerable proportion of inorganic salts⁴ ordinarily found in normal urine," together with materials introduced⁵ in Moor's purification process. We concluded further, that "its toxicity may be referred to some of these normal urinary constituents.⁶ Consequently, our knowledge of the cause of uremia, much as it is to be regretted, has been in no way increased by Moor's work on ureine, nor can any of his deductions regarding the biologic significance of this urinary complex be accepted."

The experiments in this laboratory were completed in December, 1900. About the same time several other investigators were making independent observations that led to the same general conclusion—that "ureine" is at best merely a mixture of urinary constituents.

¹ Moor: Medical Record, September 1, 1900, lviii, p. 336, and September 22, p. 471.

² Chace and Gies: Medical Record, March 2, 1901, lix, p. 829; also Gies and collaborators: Biochemical Researches, 1903, i, p. 595 (Reprint No. 31).

³ Urea, creatinin, pyrocatechin, phenol, alkaloidal bodies, purin bases, etc.

⁴ Sodium, potassium, ammonia, phosphate, etc.

⁵ Mercury, nitrate, oxalate.

⁶ Potassium, alkaloidal bodies.

Weatherson¹ soon followed with a paper in which he stated that "not succeeding in proving that the ureine of Moor is a constituent of urine, he began a series of experiments to prove that it is not." "In this," he says, "I was more successful."

Wiesener² stated that "after going over Moor's article very carefully, I find that there is no chemistry whatever in his paper. In fact, it is an article made up simply of words, and facts relegated to the background."

Haines and Woods³ entitled their paper, "Is there such a constituent of the urine as ureine?" and gave an emphatic "No" as the answer necessitated by the results of their own experiments. They said: "Moor's article on ureine is a presentation of hasty conclusions based upon unskilful and inadequate experimentation, and upon insufficient acquaintance with the known chemistry of the urine."

Kuljabko⁴ found that ureine is a mixture of creatinin, pigments, urea, inorganic salts, and unidentified substances, and regarded it as identical with "Pouchet's urinary syrup" ("matière extractive de l'urine").

No less than 4 different experimental investigations, conducted independently at about the same time in as many laboratories, led to results that were practically identical, and to the conclusion that the claims put forth by Moor for ureine were unfounded. No one known to me has been able to confirm Moor's results.

Moor seems to have paid no attention to the conclusions in this connection of his American colleagues, but answered Kuljabko with a repetition of the old claims,⁵ and a presentation of a modified method for separating ureine more perfectly. The modified method is no more convincing, however, than the first, and appears to have as little real chemie foundation. Lately Moor⁶ has again referred to ureine as a substance about which no further doubt need be felt.

It will be cheerfully admitted by all who may have looked into the matter, that what Moor calls "ureine" contains unknown substances of undescribed characters, just as is the case with most urinary extracts, but the same may be said quite as definitely of the urine itself. Until Moor gives conclusive evidence that his oily product is something more than merely a residual mixture, and shows that it is a single substance of definite chemie properties and composition, it cannot be admitted that any advance has been made by him chemically or biologically.

If "ureine" is the "most characteristic component part of urine," and "superior in quantity to urea," as Moor claims it to be, our present-day information on the quantity of urea in the urine needs decided revision. Moor has fully appreciated this fact, and has at last succeeded in finding a method⁷ which he seems to think will show that the urine contains only about a half or a third of the amount of urea heretofore believed to exist normally in it, the difference in urinary nitrogenous matter consisting of ureine. But this method also appears to have important defects.

The work of Erben⁸ indicates that Moor has failed to substantiate his claims with respect to the amount of urea in urine, although Moor⁹ in a reply to Erben holds to his original position, but indicates in a footnote that he did not succeed in fully separating urea from ureine after all.

In determining the amount of urea in the urine, Moor oxidized with zinc permanganate, evaporated at about 50° C., extracted urea from the residue with amyl alcohol containing 10% of ethyl alcohol, and then ascertained the quantity of urea in the alcoholic extract by titrating with a modification of Liebig's method. "Even if the urea itself may not be decomposed in part by the zinc permanganate, it is still to be shown,"

says Schulz,¹ "that extraction of the urinary residue with amyl-ethyl alcohol, as stated by Moor, effects quantitative separation of the urea."

Folin² has also pointed out an important assumption in Moor's conclusions. Moor states that the oxidized urinary residue, after extraction with the amyl-ethyl alcohol, no longer contains any urea, and bases this conclusion on his failure to obtain from solutions of this residue any crystals of urea nitrate on treatment with concentrated nitric acid. But, as Folin points out, the formation of crystals of urea nitrate, even from concentrated urea solutions, is hindered by just such inorganic substances as this residue surely contained. Sodium chlorid, for example, will do so. Consequently one of the main props under Moor's method falls to the ground, and the method with it.

These facts make it very obvious, we think, that better chemie methods must be devised to establish the deductions which Moor has been publishing so widely with regard to the properties of "ureine" and the quantity of urea in urine. Until then revision of former views is neither called for nor possible.

DISEASE, DRUNKENNESS, ETC., AND THE POST CANTEEN.

BY

GEORGE M. KOBER, M.D.,

of Washington, D. C.

To the Editor of *American Medicine*:—I have carefully gone over my statistics, and they agree with the original sources. The introduction of the statistical tables was done to show what the conditions in the army were before the introduction of the canteen, during its actual operation, and what the indications are since its abandonment.

The statistics furnished by Mr. Johnson in the *New Voice*, December 17, with the exception of a few unimportant errors, are correct, but the use he has made of them is misleading.

While the first canteen was established with the consent of General Howard as a temperance measure at Vancouver Barracks in 1880, and a few other canteens may have been established, the system was not officially recognized by general orders until February 1, 1889, hence it is not fair to include statistics prior to 1890 as belonging to the canteen period. When Mr. Johnson's figures on desertions are classified in accordance with the facts, we find that the average percent of desertions before the canteen period was 10.1%, the average during the whole canteen period 1890-1900 (11 years) was 4.9%, and for the years 1902 and 1903, i. e., during the operation of the anticanteen law, the average was 6.4%.

A similar classification of the court-martial table shows the average during the anticanteen system to be 78 per 1,000, during the canteen system 64.9, and for the 2 years 1902 and 1903, 68.5 per 1,000.

The admissions for alcoholism were for the respective periods 45.78, 28.03, and 25.12, but please note in each instance the direction where we are drifting.

In regard to saving deposits, my deductions were based upon the figures reported by the paymaster-general and quoted by Dr. Munson, on page 89 of his "Military Hygiene," showing that the average number of men annually making such deposits for the 7 years 1885-1891 was 7,273, while for the 6 years 1892-1897 the average so depositing was 8,382, an increase of 13.3%. This indicates not only increased contentment, but a decidedly improved moral tone, and means that over 1100 additional depositors were created, thus practically giving bonds to the Government for good behavior. The real good accomplished, therefore, was not so much a question of the average amount deposited, but the number of men cultivating the habit of making such deposits. You will observe from the enclosed letter dated September 25, 1903, from Dr. Lynch, of the Surgeon-General's Office, that I have taken special pains to secure reliable information upon all points where there was a

⁹ Moor: Ibid, xl, p. 162.

¹ Schulz: Chemische Zeitschrift, 1903, lii, p. 189.

² Folin: Zeitschrift für physiologische Chemie, 1903, xxxvii, p. 548.

reasonable doubt, and I have only to add, that the statistics presented by me for the several periods, and the conclusions drawn therefrom must speak for themselves.

Dr. Day's figures and arguments are evidently taken from *The New Voice* of December 17, which I returned to you with comments, clearly indicating that if any juggling with figures has been done it can be charged to the author of that article. I have simply given the figures from official sources, and the conclusions drawn by the committee must speak for themselves. In regard to table in first column, p. 908, please consult Munson's *Hygiene*, p. 819; the information for subsequent years was obtained from the office of the Judge Advocate-General, and is correct with the exception of a typographical error in 1901, which should be 5,973, instead of 6,065, without a change, however, in the second column, which is the important column. The classification of the table in the second column on p. 908, is in accordance with the facts, as the canteen was not recognized officially until February 1, 1889.

I know nothing about the delayed expenditures for the soldiers' club-rooms and gymnasiums, and cannot believe that whisky was ever sold to our soldiers in the canteen, and, in fact, so far as my personal observations extend, very little wine was ever sold.

The enclosed letter from Paymaster-General, dated September 24, 1903, indicates that the table regarding the soldiers' deposits was prepared at his office.

WAR DEPARTMENT, PAYMASTER-GENERAL'S OFFICE, WASHINGTON.

September 24, 1903.

Dr. George M. Kober, 1600 T street, N. W., Washington, D. C.

Sir:—Enclosed please find a statement in regard to deposits by soldiers of the U. S. Army for the past 5 years, also copy of my letter to the Adjutant-General of November 28, 1902, in regard to the increase in collections on account of fines and forfeitures since the abolishment of the canteen; and supplemental to the letter, a statement of collections for the past fiscal year.

Very respectfully,

A. E. BATES, Paymaster-General, U. S. Army.

* Including scouts.

Respectfully furnished Dr. Kober at his request.

WALTER D. McCaw,
Major, Surgeon, U. S. Army.

The figures for alcoholism have been verified and found to be correct. The rate for the Pacific Islands, not including the Philippine Scouts for 1902, is 21.10, and that of the whole army not including the scouts is 24.02.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE, WASHINGTON.

September 25, 1903.
Dear Dr. Kober:—Please find enclosed the statistics you requested from me yesterday. I think I have found our error, and that alcoholism has in fact increased. By reading the note at the foot of page 1 you will see that the rate for the Philippines has really slightly increased for 1902, and the rate for the whole Army is really somewhat higher than for 1901. In both the Philippine Scouts have been excluded, which should be done, as alcoholism is very rare among them, and would not be affected one way or the other by a canteen. Scouts were first included in the latter part of 1901, but they were not separately tabulated for that year, and I am unable to give the figures. They would not greatly change the percentages as written.
If I can be of any service, please command me.
Very respectfully, CHARLES LYNCH.

THE ARMY SALOON.

BY
GRAFTON E. DAY, M.D.,
of Millville, N. J.

To the Editor of *American Medicine*:—As one who has taken a lively interest in *American Medicine*, I have been much pained by the attitude taken by your journal on the canteen question. So far as my memory serves me I do not recall seeing a word favorable to the action of Congress and unfavorable to the failure of officials to carry out the provisions of the anti-canteen law, by which nearly 2 years ago Congress appropriated \$500,000 for gymnasiums, libraries, etc., for the army posts, and how last winter another \$500,000 was appropriated for the same purpose, and how from this entire million dollars not a trapeze is in operation, not a solitary book has been bought, not a single dumb-bell has been added to the army equipment. This money was appropriated for the purpose of giving the soldier boys recreation and a place for the same, apart from the influences of the army saloon, for as Lieutenant-General Miles says: "Now that liquor has been removed from the military reservations, those not addicted to its use are free from its demoralizing influences. The temptation to use it is made very remote." Further, he says, "It is folly to suppose that a man is going to drink as much liquor if he has to go from half a mile to 5 miles to get it as if it were constantly served in the room where he is located. There is no more reason for a saloon at an army post than at any well-conducted college or university, or at West Point, or at the Soldiers' Home at Washington."

Your editorial comment of December 12 accepts as facts what Dr. Kober says, and you proceed to say things that had better been left unsaid, were the facts known to you. Permit me to say first, that Lieutenant-General Miles has given his unqualified endorsement to the present law, and in several

reports he has taken an advanced position against the army saloon. We have not heard that General Miles was particularly noted as a temperance reformer, but the General has acquired some reputation as one who knows what is best for the army of the United States. In your editorial comment referred to, you assume that only light wines and beer are sold in the army saloon, whereas incontrovertible evidence in abundance has clearly proved that whisky was sold in very many, if not all the army saloons.

Allow me, if you please, to take up very briefly several tables given by Dr. Kober, and in doing so let us frankly face the situation that there has not been a single authentic instance where any brewer or distiller has favored the present law relating to the canteen. This, too, in the face of statements that have appeared in *American Medicine*. In the first table of "alcoholism," Dr. Kober gives "admissions to hospitals," which seems scarcely fair since all reputable authorities use "admissions to sick list." Yet in Dr. Kober's figures we have an average of 36, against 25.13 for the no-canteen period, and taking the canteen period beginning with 1889, we have an average of 29.59, against our 25.13.

The table on page 908, first column, must be one arranged for the occasion, since I am reliably informed that there are no such tabulations compiled officially, my authority stating positively that there are no such statistics compiled in the army as given in the second column of the table referred to. The first table in the second column, page 908, is garbled by making an entirely new classification of the canteen years to make the figures come out right. The table in regard to "statement," showing the savings deposits, is especially crooked, "the scamps have taken the deposits for the entire army and divided it by the number in the regular army alone." Can one who would do this be trusted to treat the rest of the question fairly? And now we come to the figures relating to venereal diseases, and here the author proves our case clearly since the increase of venereal diseases can be very satisfactorily explained when we remember that the canteen theory is in operation in the Philippines, as to vice, they having never really abolished the certified prostitute business there.

Their figures for insanity are against them. The figures given by Dr. Kober are from a book that weighs about 4 pounds and contains briefs in favor of the army saloon and army prostitutes. It is hardly honest to quote such a one as authority when trying to consider this question fairly.

Then, too, it is more than unfair to clamor for the restoration of the army saloon when the provisions made by Congress to provide places of recreation and relaxation safe from the seductive influences of liquor have not been availed of. Just one remark as to the record of the canteen when provided with a saloon. After Dewey's victory, when the army saloon had been in operation practically for 13 years and officially for 8 years, the very flower of the army was sent to the Philippines. The result was that in the first 10½ months more than one-half of this army had been court-martialed, as was shown by the first annual report of Major John A. Hull, Judge Advocate of the Military Department of the Philippines. The report covered a period up to the close of the fiscal year, June 30, 1899. During these months there was an average number of 21,078 enlisted men in command, yet during this time there were 12,481 cases of courts-martial of various sorts. Thus, according to official reports, covering the first 10½ months of the American occupation, there was held an average of 38 courts-martial a day for the entire period, among the average total of 21,078 soldiers. This was a canteen record. It was solely because of its deadly work that Congress outlawed it, and for no other reason.

Congress did not deprive the soldier of his beer.
Congress did not close up the exchange or club.
Congress did not forbid the soldier to drink beer.

But Congress did order the army to get out of the saloon business.

Finally, allow me to quote further from Lieutenant-General Miles. "For a long time the army has been without what is known as the liquor feature of the canteen. The army posts are much better off without it, I find. That element having once been discarded it would be an injury and a backward step

to reintroduce it. The canteen, so-called, is a recreation room or building established or set apart at nearly all military posts for the comfort of the enlisted men. It includes a recreation room which gives the men opportunity for social intercourse, the playing of games, and the reading of magazines and books. It also affords them light refreshments of various kinds which they may desire, in addition to the good wholesome food furnished by the government. There are certain men in the service as in every community, who will have liquor if it is possible to obtain it. Of course these are not the best men in the ranks. Beside, the amusement rooms where the men may study or read, or have orderly recreation, are not disturbed by men wholly or partly under the influence of liquor.

"In other words, the canteen is made inviting to decent, self-respecting men. This I say positively from my own observation. At one of the large posts in the West, the present canteen is so well patronized that it has paid dividends of \$1.00 a month to every man. This shows that the argument that the canteen cannot be sustained without the liquor feature is wholly false. Many years ago liquor was furnished as a part of the rations of each soldier and officer. Gambling and dueling were formally prevalent in the army, but both have disappeared. Efforts have been made to make the young men in the army orderly, sober, and intelligent, giving them all the facilities for recreation, athletic sports, and outdoor exercise." When asked as to what influence was working for the restoration of the saloon feature, while General Miles did not positively implicate the liquor trust, he said, "certain influences I would not care to discuss, but not in the best interests of the army, however."

Now, Mr. Editor, will you give more credence to "Munson" with his unsavory book, to Dr. Kober, who has juggled with figures, or will you give Lieutenant-General Miles credit for knowing most about this question? The "Reports of Officers," as you know, may be entirely unimportant, depending upon circumstances, and further, many of us know that in that document, favorable reports for the law from General Joe. Wheeler, General Shafter, and Lieutenant-General Miles were not allowed to appear. It is unbelievable, if it were known (and who did not know?), that Secretary Root and others in authority were working for the restoration of the army saloon, that any number of Colonel Nobody's, Captain Somebody's father's sons, etc., could be found to send just such reports as were desired.

THE PRICES OF DIPHTHERIA ANTITOXIN OF THE SO-CALLED "TRUST."

To the Editor of *American Medicine*:—Our attention has been called to a sensational article appearing in the Chicago papers, in which the manufacturers of antitoxin are charged with having formed a trust and advancing the prices of diphtheria antitoxin, this advance being prejudicial to the best interests of the public health, and inimical to the best interests of the medical profession.

It is not true that the antitoxin manufacturers have combined in a trust; it is not true that the prices of antitoxin have been advanced, but to the contrary the prices of antitoxin have been reduced when quality of serum is considered.

So that you may have a clear understanding of the situation we beg to advise the following:

For a long time the different manufacturers have endeavored to improve the quality of diphtheria antitoxin. It has formerly been the custom to manufacture 2 strengths, known as Standard and Concentrated, or X and XX. There were also supplied certain sizes, known as 500 units and 1,500 units packages. There is now but one strength of antitoxin that will be placed on the market, and that will be practically the highest strength, formerly known as Concentrated Serum. This is the best quality of serum obtainable, and on this quality, instead of the prices being advanced, they have been materially decreased. For instance: For the 1,000 units there is now a charge of \$2.00, against a former charge of \$2.25; for the 2,000 units there is now a charge of \$3.50, against a former charge of \$4.00; for the 3,000 units there is now a charge of \$5.00, against a

former charge of \$5.75; for the 4,000 units there is now a charge of \$6.50, against a former charge of \$7.50.

The 500 units and 1,500 units packages have been discontinued, the 500 units being insufficient to insure thorough immunization, and the 1,500 units on account of its small demand.

You will thus see that the interests of the medical profession have been safeguarded, inasmuch as but one strength—and that the best—will insure the highest quality of antitoxin being furnished. The revision of prices is also decidedly in favor of the physician and his patient, because the physician is now able to get the best grade of antitoxin at a lesser price than formerly charged.

Instead of marketing antitoxin by number as heretofore, it is sold by the units package, 1,000 units representing an immunizing dose; 2,000 units, a small curative dose; 3,000 units, a moderate curative dose; 4,000 units, a full curative dose. This style of nomenclature makes it easier for the physician than heretofore, and since the best quality of antitoxin is sold at a lesser price, it will prove an additional incentive to use full doses, which all authorities recommend in order to secure the best results from antitoxin.

Every manufacturer today is striving to meet the demand for the most convenient means of administering antitoxin, and while the improvement in package by which every dose of antitoxin is furnished in an aseptic serum-syringe, including sterile needles, has entailed considerable expense to the manufacturer, it is offered at a less cost to the physician.

There was formerly some of a lower grade serum used, and we feel sure that its discontinuance will be of material advantage.

It is possible that the Chicago Board of Health may be compelled to pay more for its antitoxin. If so, it is only just, as it had been quoted a price that does not yield sufficient remuneration to anything like cover the expense involved in producing. However, the Chicago Board of Health will now be able to get a better quality of serum than was formerly used, as the weaker strength, which it formerly used, has been entirely discarded.

We hope that you will place this matter in the true position before your readers, in order that they may understand that there is no truth whatsoever in the sensational reports relative to the so-called "trust or combination" of the manufacturers of antitoxin, and the statement that the prices have been raised when, as a matter of fact, the former prices are considerably reduced.

Very truly yours,
H. K. MULFORD COMPANY.

By
H. K. MULFORD.

NEED OF A WARD IN GENERAL HOSPITALS FOR INSANE PATIENTS.

BY
THEODORE DILLER, M.D.,
of Pittsburg, Pa.

Neither Dr. Rhein nor Dr. Peterson, in discussing the need of a ward for insane patients in general hospitals, seems to be aware that St. Francis, a general hospital in Pittsburg, has for a number of years provided several wards for this purpose. These wards have been of the greatest benefit to the insane of this city. Those who leave St. Francis Hospital do not carry with them the stigmas of insanity in anything like the same degree as do those who leave a regular "lunatic asylum."

I sincerely trust that Dr. Rhein's plea may bring forth fruit. If one or two general Philadelphia hospitals were to provide wards for sick persons who exhibited the symptom-complex called "insanity," much practical and theoretic advantage would be gained for the city, for the "insane," their families, and for the profession in the city.

Such a ward in connection with one of the hospitals associated with one of the medical schools in Philadelphia would be of inestimable value as an object lesson to students. May Dr. Rhein's plea stir up at least one of the Philadelphia hospitals to adopt his suggestions!

ACUTE LOBAR PNEUMONIA: AN ANALYSIS OF 486 CASES, AND OF 100 AUTOPSIES.

BY

JOHN McCRAE, M.B. (Tor.),

AND

J. C. FYSHE,

AND

W. E. AINLEY,
of Montreal, Can.

From the Montreal General Hospital.

PART I.

The cases here tabulated constitute undoubted cases of primary lobar pneumonia admitted to the wards of the Montreal General Hospital, from January 1, 1895, to August 1, 1903; the autopsy analysis has not been made as a continuation of the clinical observations, but as a distinct series, which, in many particulars, gives the truer frequency of a complication, or the higher percentage of occurrence of some detail which is difficult to observe during life.

The entry into hospital by months is tabulated, and it is worthy of remark that the weather from December 1 to March 15, is generally steady cold; March 15 to June 1, very changeable, with considerable rain, June 1 to October 1, warm and dry; October and November, cool and dry. The heavy snowfall of winter melts in April, and during that month, though bright overhead, it is scarcely ever dry under foot.

	No. of cases.	Percent of cases.
January.....	39	8
February.....	55	11.3
March.....	58	11.5
April.....	74	15.2
May.....	80	16.4
June.....	33	6.8
July.....	26	5.4
August.....	15	3
September.....	14	2.8
October.....	27	5.5
November.....	25	5.1
December.....	42	8.6

The largest number of cases occurs in these changeable spring months, but as soon as summer is established the prevalence gradually lessens throughout the whole season, only attaining a moderately high figure after the setting-in of winter. It is not improbable that wet streets have a large share in the causation of spring pneumonia, and the intense steady cold of winter a less effect than would be expected.

Sex.—Three hundred forty-eight (71.6%) were males, 138 (28.4%) females.

Mortality.—The deaths numbered 104 (21.2%).

Whereas less than 20% of cases in the male were fatal, more than 25% of the cases in the female were fatal.

Age.—The ages divided into periods are given:

Age in years.	No. of cases.	Percent of cases.	No. of deaths.	Percent of total deaths.	One patient died in every
1 to 3.....	16	3.3	5	4.9	3
4 to 15.....	67	13.9	5	4.9	13
16 to 22.....	70	14.5	5	4.9	14
23 to 31.....	98	20.3	19	18.4	5
32 to 41.....	92	19.1	19	18.4	5
42 to 51.....	84	17.4	29	28.1	3
52 to 61.....	33	6.8	11	10.7	3
62 and over.....	22	4.5	10	9.7	2

It will be noticed that after the age of 40 the chances for recovery are gravely lessened, whereas the mortality in youths, 16 to 22, is a comparatively low one, although the number of cases is perhaps greater than in any other half decade. Yet as an indication of the fallacy of making a prognosis upon the youth of the patient, it may be

said that the approximate average age of patients who died was 37.7 (average of 100 autopsies, given below, 38.8), while the average age of the patients who recovered was 35.5; these 2 averages show much less difference than one would expect.

Etiology.—Previous attacks had occurred in 53 out of 425 cases, 12.4%, or approximately 1 in 7, a percentage of occurrence much lower than is usually found (Osler's "Practice of Medicine," iv ed., p. 109); in 372 cases, previous attack is noted as not having occurred. Of the 53 cases, 3 patients had had 3 or more previous attacks, one had had 2, and the others 1.

Tuberculosis.—Of 462 cases, family history of tuberculosis was present in 31, personal in 20, and 9 had had previous pleurisy, a total of 60 (13%) in whom there is likelihood of tuberculosis having preceded the disease.

Race.—During the summer and autumn months a large number of immigrants pass through Montreal, and it has been a frequent comment in the hospital that a good many poorly-nourished Europeans, chiefly Italians, are brought in suffering from pneumonia, shortly after landing. Of 456 cases of our series, 74 (16%) were immigrants, defined as having been less than 6 months in the country. From the Government statistics of the number of immigrants, and the most careful estimate at which we can arrive of city population, this indicates that the immigrant is at the very least thrice as liable as the native.

Occupation.—We have endeavored to ascertain what proportion of the population of Montreal is employed in outdoor work, and this we find difficult, because of the great differences of conditions, due to climate, between summer and winter. Of 444 patients, 126 (28.4%) were engaged in outdoor work; 318 (71.6%) in indoor occupations; if we allow that a fifth of the population is engaged in outdoor work, (this figure is probably too high), the outdoor worker has suffered 1½ times as frequently as the indoor worker; if we allow that 1 to 10 only of the population is so employed, the outdoor worker is 3½ times as liable. In any case our figures tend to show that the outdoor worker is more frequently attacked.

The Use of Alcohol.—Of 190 cases in which the records are explicit, 62 (32%), were alcoholics, 92 (46%), moderate users of alcohol, and 32 (19%), were teetotalers. This question of the liability of alcoholics to pneumonia, is so complicated by other questions of etiology, such as poverty, irregular habits, etc., that it is impossible to set a positive value upon figures.

Influenza.—Acute influenza preceded the disease in 5 cases.

Catarrh.—Catarrh, defined as chronic inflammation of the upper air passages, was present in 90 cases (20.3%), in 90% of which cough was present.

Duration.—The average length of time from onset until discharge from hospital (at which time the patient is presumably able to return to work), was in 351 cases, 27.5 days.

Crisis and Lysis.—Two hundred and twenty-six (60%) ended by crisis, 106 (28%), by lysis. In 48 cases (12%) the fall of temperature was atypical. The fatal cases have, of course, been excluded from this calculation.

Of 211 cases in which the precise time could be determined, crisis occurred after the lapse of 7.1 days; in 106 cases of fall by lysis, the fall of temperature began after the lapse of 8.4 days; the cases of early crisis are not sufficiently authentic to state. Delayed resolution was found in 9 cases, 1.9%.

Fever.—The height of the fever is classified below:

	Degrees.	No. of cases.	Percent of cases.
Low.....	99 to 102	81	17
Moderate.....	102 to 104	245	52
High.....	104 and over.	146	31

Onset.—It has been noted that in 90 cases there were previous catarrhal symptoms, 72 of these patients having cough. Of the usual symptoms of onset, the frequency was as follows:

	Percent.
Cough (including patients with cough previously).....	100
Pain.....	92.1
Chilly sensations.....	70
Vomiting.....	35
Rigor.....	6.1

The pain was never referred to a region other than the seat of disease.

Symptoms.—Respiratory system. Rusty sputum was present in 195 cases out of 434 (44.9%), bloody sputum in 7 cases, and dilated *alae nasi* in 190 (40%).

Nervous System.—The border line between delirium and mania is not a distinct one:

	Cases.	Times.	Percent.
Headache in.....	437	184	42
Delirium in.....	447	157	35
Mania in.....	447	8	1.8
Convulsions in.....	447	8	1.8

The cases of delirium were analyzed with respect to an alcoholic history; 93 cases (59.2%), occurred in non-alcoholics; 64 cases (40.8%), occurred in alcoholics. Of 62 heavy drinkers, 37 (59.6%) were delirious; of 92 moderate drinkers, 27 (29.3%) were delirious; of 154 users of alcohol, 64 (41.5%) were delirious.

All the cases of convulsions mentioned occurred in children with the exception of one, a girl of 25, nonpregnant, who recovered without apparent complication.

Alimentary System.—The condition of the bowels, if at all disturbed, has tended toward constipation.

Of 460 cases, the bowels were normal in 242 (57%); diarrhea in 55 (12%); constipated in 143 (31%).

Jaundice is remarkably infrequent in this series, having occurred in 465 cases but 18 times, a frequency of 3.8%.

Urine.—In view of the likelihood that every case of pneumonia is attended with a temporary kidney damage, it is interesting to note that this does not appear in the routine examination of the urine. Of 450 cases, albumin was found in 22%, casts in 1.5%, both together in 25.7%; pus, dependent, in all likelihood, upon associated conditions, was present in 6.6%.

Quantitative examination of the chlorids has been made in a disappointingly small number of cases; of 16, 4 showed normal, 3 increased, and 9 (56%), decreased excretion of chlorids. Examination of the sediments, though tabulated in more than 100 cases, does not seem to be of sufficient value to merit reproduction.

Various.—Sweating, sufficiently profuse to be recorded, exclusive of the sweating of crisis, was found in 139 out of 434 cases, a frequency of 32%. Herpes was present 124 times in 475 cases (26.1%); epistaxis occurred 12 times (2.5%); the spleen was found to be enlarged in 30 cases (6.4%); the liver in 3 cases, excluding chronic cirrhosis. Erythema occurred twice, and a petechial rash once.

Vascular System.—From stated measurements which we have gone over in 465 cases, it was determined that definite cardiac dilation was present in 85 cases (18%); this, no doubt, marks the number of extreme dilations, and entirely fails to include the slight rightsided dilation that must accompany every case of pneumonia with large involvement of lung. Considering the difficulty of observing slight degrees of dilation at autopsy (see below), it is not strange that they should not be observed in life while the chest wall intervenes. That cyanosis is noted in 15% of all cases, and accentuated pulmonary second sound in 16%, implies failures to record these almost invariably present signs.

Leukocytosis.—Considering 7,500 as normal, leukocytosis occurred in 43 out of 45 cases (95.5%); 32 patients

who recovered showed figures varying from 8,400 to 34,000, average 22,000; 11 patients who died varied between 9,800 and 50,000, and averaged exactly the same, viz., 22,000. Of these 11 deaths it should be mentioned that in 5 there were severe septic complications, which would in every case naturally lead to leukocytosis.

Distribution of Disease.—Of 473 cases the involvement was as follows:

	Cases.	Percent.
Right lung only.....	226	48
Left lung only.....	141	30
Both lungs.....	106	22

Of bilateral cases, 31% terminated fatally, 15% of the left lung cases, and 21% of those in which the right lung was affected. In 5 cases all lobes were affected, and 2 (40%) recovered. It is a coincidence that the number of cases in which 3 or more lobes were involved, was 104, exactly the number of deaths in the series.

	Cases.	Percent.
One lobe was affected in.....	190	40.1
Two lobes were affected in.....	179	38
Three lobes were affected in.....	94	20
Four lobes were affected in.....	5	1
Five lobes were affected in.....	5	1

The most frequent involvements were as follows (473 cases):

	Cases	Clin. series. Percent.	Autopsy series. Percent.
Lower left.....	81	17	5
Lower right.....	67	14	7
Middle and lower right.....	53	11	4
Whole left.....	46	10	17
Whole right.....	44	9	18
Upper and middle right.....	25	5	2
Both lower.....	25	5	3
Upper right.....	22	5	5
Whole left and lower right.....	16	3	2
Lower left and middle and lower right.....	15	3	3
Upper left.....	14	3	4

The mortality for 3 lobes or more was 46.1%.

If any one should be interested in the frequency of any given combination of lobes, we append our full figures, asking the forbearance of the general reader for the following table:

	Clin. series. Percent.	Autopsy series. Percent.
Lower left and upper and lower right.....	1.6	5
Whole right and lower left.....	1.2	3
Upper left and upper right.....	1.2	1
Whole of both lungs.....	1	1
Lower left and upper right.....	1	0—
Whole left and lower and middle right.....	.6	0—
Upper left and upper and middle right.....	.6	1
Upper left and lower right.....	.6	2
Whole left and upper right.....	.4	0—
Whole right and upper left.....	.4	3
Upper left and middle and lower right.....	.4	0—
Lower left and middle and upper right.....	.4	1
Whole left and upper and lower right.....	.2	3
Whole left and upper and middle right.....	.2	0—
Lower left and middle right.....	.2	2
Upper left and upper and lower right.....	.0—	1
Middle right.....	.2	0—
Upper and lower right.....	1.6	0—

It will be observed that there is little or no correspondence between the figures of the 2 series, a fact which is explained by the comparative rarity of all these combinations.

In the autopsy series, the lobes have been involved in the following order of frequency, beginning with the one most often attacked—lower right, upper right, lower left, middle right, upper left.

As to how far the prognosis is based upon the extent

of lung tissue involved, we may state the following: In the clinical series, 22% had 3 lobes or more involved (mortality in these cases 46.1%), and in the autopsy series, 41% had this involvement, which figures, so far as they go, tend to show that prognosis is in some degree based upon the amount of lung tissue implicated.

Treatment.—The methods are very variable, and have been tabulated without any comment. In 40 there was practically no treatment. Hydrotherapy (baths) was used in 45 cases, all within the last 2 years; expectorants were given in a third of the cases, medicinal analgesics (morphia, heroin, coaltar products, etc.) in one-tenth of the cases; ice and heat were used in one-fourth of the cases; stimulants in three-fourths; venesection was practised in only 1 case. The above really indicates a prevailing tendency throughout the series toward a symptomatic treatment with ready recourse to stimulants.

Complications and associated conditions.	No. of cases.	Percent of cases.
Pleuritis.....	163	34.3
Meningitis.....	23	4.7 (8 cases proved by autopsy.)
Otitis media.....	19	4.1
Empyema.....	18	3.8
Emphysema.....	28	6
Ac. endocarditis.....	16	3.4
Ac. pericarditis.....	11	2.3
Myocarditis.....	14	3
Thromboses.....	4	
Saphenous.....	2	
Cerebral.....	1	
Sup. long sinus.....	1	
Tonsillitis.....	6	
Parotitis.....	4	
Erysipelas.....	4	
Peritonitis.....	3	
Abscess (of back).....	1	

Associated conditions.	No. of cases.	Percent of cases.
Arteriosclerosis.....	39	8.3
Cardiac valvular defect.....	32	6.8
Mitral stenosis.....	2	
Mitral regurgitation.....	19	
Tricuspid regurgitation.....	1	
Anemia.....	8	
Angina pectoris.....	1	
Paralyses.....	6	
Aphonia.....	3	
Facial.....	1	
Third nerve.....	1	
Paraplegia.....	1	
Neuralgia.....	2	
Facial.....	1	
Sciatic.....	1	
Epilepsy.....	1	
Cirrhosis liver.....	5	
Pregnancy.....	5 (abortion in 4.)	
Nephric abscess.....	2	
Orchitis.....	1	
Gonorrhoea.....	1	
Syphilis.....	2	
Malaria.....	2	
Typhoid.....	2	
Measles.....	2	
Rheumatism, chronic sic].....	4	
Rickets.....	2	

We have purposely refrained from comment upon these complications, because we feel that in many cases such as pleuritis, empyema, etc., the autopsy findings are distinctly more valuable. One cannot be sure that the so-called complications are really such, or should more properly be included in associated conditions. At the same time we have not felt justified in omitting them from a strictly statistical article.

PART II.—ANALYSIS OF 100 AUTOPSIES.

The autopsies are partly comprised in the cases analyzed from the wards, but to complete the number it was necessary to go back as far as the record of 1890; so that for purposes of comparison the 2 series are essentially different. All the cases are selected with a view to the exclusion of those in which the pneumonia could be considered secondary to any other disease, by which carefulness one doubtless rejects many cases which are

true lobar primary pneumonia, occurring in those slightly debilitated by some other cause; so that the series is really a synopsis of cases of pneumonia arising in the comparatively healthy. It is obvious that one must not rule out cases occurring in those past middle life with marked kidney change, or else the search for cases would be interminable. The numbers throughout designate percentages, as well as numbers of cases; in many cases comparisons are instituted between these figures and the figures of the same conditions obtained by clinical observation.

Sex.—Seventy-seven cases were in the male and 23 in the female.

Age.—The average age of the patients was 38.8 years. The average age of all the patients in the previous series was 31 years.

Age by periods.	Autopsy series. Percent.	Clin. series. Percent.
1 to 3.....	3	4.9
4 to 15.....	1	4.9
16 to 22.....	6	4.9
23 to 31.....	17	18.4
32 to 41.....	26	18.4
42 to 51.....	28	28.1
52 to 61.....	11	10.7
62 and over.....	8	9.7

It is to be noted that there is a striking similarity in the percentages, especially after the age of 15, when the number of cases in each period becomes at all considerable.

Involvement of	Autopsy series. Percent.	Clin. series. Percent.
Right lung.....	43	48
Left lung.....	26	30
Both lungs.....	31	22
Five lobes.....	1	1
Four lobes.....	9	1
Three lobes.....	31	20
Two lobes.....	38	38
One lobe.....	21	40

The conclusion derived from this comparison is, that the amount of lung tissue involved has a very direct bearing upon prognosis, since so comparatively few one-lobe cases, and so many three-lobe and four-lobe cases appear in the autopsy records.

Stage of Disease.—Of the cases in which the color of the lung is mentioned, red hepatization was present in 23%, gray in 55%. This indicates roughly that in a majority of cases the lung is gray in color, due oftener at autopsy to purulent infiltration than to a true gray hepatization, which we are accustomed to think of as a first stage in resolution. It might be said in this connection that the classic division of pneumonia into stages, has misled, and will continue to mislead, many into the supposition that these are hard and fast sequences following a rule, rather than hazy indications of the progress of the disease, which in most cases encroach upon one another so greatly as to lose their individual characters.

Infection.—Of about 60 cases in which bacteriologic examination has been made, pneumococcus was present in 65%, in 5% of which it was mixed with other organisms to the extent of being a "mixed infection;" 20% were mixed infections of other kinds, while streptococcus was the main agent in 8%. While dealing with the kinds of infection, it is of interest to note the effect of the different ones upon the size of the spleen. The late Dr. Wyatt Johnston on one occasion remarked that he had observed that the spleen was rarely enlarged in cases of infection by pneumococcus, while it was frequently enlarged in other infections. With a view to determine this, we have tabulated the results as follows:

In 23 cases infected by pneumococcus alone, the spleen was not enlarged in 19 (83%), and was enlarged in 4 (17%);

in 12 cases of mixed infection, without pneumococcus, it was not enlarged in 4 (33%), and was enlarged in 8 (66%). Of 6 cases of mixed infection, including pneumococcus, it was enlarged in 3 and not enlarged in 3. Whatever the size of the spleen (180 gm. in the male adult was the standard), it was in the large majority of cases (64%) soft and pulpy. So far as the figures go, the truth of Dr. Johnston's observation is strongly supported.

Complications and Associated Conditions.—The relative frequency of certain complications in the 2 series is of interest; the discrepancies which will be seen to exist in pleuritis and pericarditis will be easily understood, when one remembers the comparatively short time in which a friction rub may be present, and the small amount of fluid which is effused in many cases. The second column exists only for comparative purposes.

	Percent.	Clin. series for comparison. Percent.
Pleuritis, total.....	91	38
Pleuritis, purulent ("empyema").....	12	
Pleuritis, serous ("effusion").....	28	
Pleuritis, fibrinous.....	51	
Pericarditis, total.....	17	3.4
Pericarditis, purulent.....	10	
Pericarditis, fibrinous and serofibrinous.....	7	
Endocarditis, acute.....	8	3
Endocarditis, chronic (associated condition).....	23	
Myocarditis, acute.....	4	2.3
Myocarditis, chronic (associated condition).....	8	
Arteriosclerosis, extreme (associated condition).....	8	
Dilation of right heart.....	18	18
Dilation of left heart.....	10	
Clots in heart chambers.....	42	
Meningitis, purulent.....	5	4.7
Bronchitis, acute.....	61	
Bronchitis, chronic (associated condition).....	6	
Nephritis, total.....	78	
Nephritis, acute parenchymatous (cloudy swelling).....	45	49
Nephritis, acute, suppurative.....	1	
Nephritis, chronic.....	52	

Of the cases of pericarditis, 7 occurred with involvement of both lungs, 4 of the left, and 5 of the right lung, supporting the frequency of occurrence with disease of the left lung.

Of the 5 cases of meningitis, pneumococcus was found in the meninges in 4; it also was found in 1 case of ulcerative endocarditis upon the heart valves, and in 4 cases of septic pericarditis.

Seven cases of abscess of the lung occurred, and 1 case of abscess of the abdominal wall; mediastinitis occurred twice; peritonitis, once; icterus was noted but once; and tuberculosis, obsolete, or obsolescent, 8 times.

NOTE.—Special interest attaches to the following points in this series:

1. The liability of immigrants to the disease.
2. The frequency with which people of outdoor occupations are attacked.
3. The infrequency of the rigor of onset.
4. The nonenlargement of the spleen in most cases of pneumococcus infection.

The apparently awkward divisions of the age tables may be better understood if we explain that a patient is classified in the column in which belongs the figure he states as his age in years.

Results in Manipulative Treatment of Congenital Hip-joint Dislocation.—According to newspaper reports, comparisons showing success in the treatment of congenital hip disease by manipulation were made in a report presented before the Society of Medical Improvement, at a meeting in Boston, January 7. The results noted were obtained by investigation and study of cases by the surgical staff of the Boston Children's Hospital. They showed that previous to the treatment by manipulation, from 1896 to 1902, only 12 cases resulted successfully, while 13 were failures. Under manipulation in 1902, 11 cases were successful, and 4 failed. In 1903 the successful cases numbered 24, and the failures 6. The doctors state that they now believe that patients up to 10 years of age may be successfully treated by manipulation.

THE BLOOD IN ACUTE LEUKEMIA.

BY
LOUIS V. HAMMAN, M.D.,
of Baltimore, Md.
Former House Physician, New York Hospital.

CASE I.—Lucia M., aged 37, an Italian, married, was admitted to the New York Hospital (service of Dr. Lambert), July 31, 1901. She died August 3, 1901. The following history was obtained from her husband. Since their marriage 8 years ago she has never been ill. Husband denies venereal contagion. Patient had 2 miscarriages after her second child. Has never had any bleeding before. The husband thinks his wife is 6 months' pregnant. She has not menstruated for this length of time. She had been quite well before the onset of this illness. Two weeks ago she had some uterine pains and thought she was about to abort, but they quickly subsided. On July 26 she had pain in the left side of chest, which soon disappeared, but was followed by pain in the left shoulder and all over the body. On July 27 the husband noticed her gums were bleeding, and this has persisted since then. She has had a little fever and profuse perspiration, but no chills. Her legs have been a little swollen since the onset of the illness. Complains of severe headache and cannot sleep. Has had no cough. Vomited only once on day of admission. Bowels have been moved twice daily by injections. Stools have been black.

Examination on Admission.—Patient is a well-nourished woman, but very anemic. Respirations are rapid and a little labored. Tongue is swollen, dry, and cracked. Gums are swollen, soft, and bleeding. There is marked dilation of the veins of the chest. Areas of hemorrhage into the skin, over the upper part of each buttock, over the right thigh, and at both ankles, are seen.

Lungs are negative. Heart: Systolic murmur is heard over the aortic and pulmonary areas. Otherwise normal. Pulse is rapid, regular, and of diminished tension. Abdomen is distended; slight movable dullness is observed in the flanks. There is no fluid wave. Pregnant uterus is felt at the level of the umbilicus. Liver: Edge is felt an inch above the umbilicus. Dullness starts at the fourth rib. Area occupied by the liver is very tender. Spleen: Edge is felt 3½ inches below the costal margin. Temperature 103.6°. Respirations 48. Pulse 132.

The patient was in a dull, stupid condition on admission, and this gradually developed into profound coma. Her respirations became more rapid and her pulse weaker, and she died without any appreciable change in the physical condition. During the 3 days she was in the hospital there was constant oozing of blood from the gums. A stool on August 1 consisted of dark decomposed blood.

Urine: Pale, cloudy, slightly reddish sediment of urates. Specific gravity 1.011, acid, no sugar, distinct trace of albumin. Microscopically: Small number of pus and epithelial cells, many uric acid crystals, amorphous urates.

Temperature varied between 101° and 104°. Respirations varied between 40 and 52. Pulse varied between 112 and 164.

Blood, July 31: Hemoglobin 35%. Red blood cells 2,050,000. Leukocytes 89,000.

CASE II.—George H., aged 56, German, carpenter, was admitted to the New York Hospital (service of Dr. Loomis), May 17, 1902. He died June 1, 1902. He complained of loss of strength, shortness of breath, and sore mouth.

History obtained in large part from his daughter, as patient's attention cannot be held long enough to obtain a consecutive narration.

Family History.—Father died of pneumonia; mother living and healthy.

Past History.—Patient denies syphilis. Has never had rheumatism or malaria. Daughter says he has always been a strong, healthy man. Was overcome by heat last summer, and was confined to the house for 2 weeks, after which he returned to work and appeared in good health until 2 months ago.

Habits.—Drinks moderately; never to excess.

Present illness began 2 months ago, when a swelling appeared on the right side of the neck and face, followed in from 10 to 14 days by a similar swelling on the opposite side. Then

glands in groin and axilla became a little enlarged. From the first he has lost rapidly in flesh and strength. Dyspnea has been a constant complaint. After a month under medical treatment his mouth became very sore, his gums swollen and tender, and his teeth loose. He has had a foul breath and marked salivation. Appetite has been poor and bowels loose—2 to 3 watery movements a day.

Physical Examination.—The patient is poorly nourished and anemic. Tongue is dry, brown and fissured. Gums are swollen and hypertrophied, and show small, shallow ulcerations. Teeth are loose and lie imbedded in a furrow in the gums, which almost cover them. Breath is offensive. Mucous membrane lining the cheeks shows numerous small ulcerations. In the right submaxillary triangle are felt much enlarged glands, each about the size of a hickory nut and fairly movable. Below this and along the anterior edge of the sternomastoid are felt several enlarged glands smaller in size and also freely movable. Similar condition on left side of neck. There is slight enlargement of the inguinal and axillary lymph glands.

Heart percusses from right border of sternum to 1 inch outside of nipple line, this point being 5 inches from median line. Upper border is at third rib. Apex beat visible and palpable in fifth interspace $4\frac{1}{2}$ inches from median line. No thrill felt. On auscultation, no murmur heard. Second aortic sound accentuated. Action strong and regular. Pulse occasionally intermits a beat and is of high tension.

Lungs are negative except for a few coarse rales over both lower lobes. Liver percusses from upper border of sixth rib to $3\frac{1}{2}$ inches below costal margin in mammary line, and its edge is indistinctly palpable $4\frac{1}{2}$ inches below costal margin. Spleen: Edge is felt about 3 inches from costal border. Abdomen is slightly distended, and shows signs of a small amount of fluid; no tenderness.

Extremities: There is slight edema of the ankles; reflexes are normal.

After admission to the hospital, patient's condition became slowly but progressively worse. His dyspnea increased, and he was soon unable to assume a prone position. His mind, which was dull and wandering on admission, became more and more clouded. Toward the end he passed into coma with Cheyne-Stokes breathing, and died a typical picture of uremia.

There was practically no change in his physical condition.

Urine: (May 20) amber, clear, sandy precipitate, acid; specific gravity, 1.014; heavy trace of albumin; abundant finely granular and hyaline casts and a few coarsely granular casts. May 21: Amount for 24 hours, 37 ounces. Albumin, 5 grams per liter. May 26: Twenty-four-hour specimen; amount, 35 ounces; amber, clear, acid. Specific gravity, 1.010; heavy trace of albumin (not measured); no sugar; few hyaline and finely granular casts; numerous uric acid crystals; total urea, 315 grains. May 28: Amount, 28 ounces in 24 hours. Total urea, 260 grains.

After this, urination became involuntary, and specimens were not collected.

Patient had a continuous fever, the temperature varying between 100° and 103.6° . Shortly before death it rose rapidly to 106.2° . Pulse varied between 112 and 138, and rose to 160 shortly before death. Respirations varied between 24 and 36, and rose to 60 shortly before death.

Blood: May 28. Hemoglobin, 42%; red blood cells, 2,800,000; leukocytes, 116,200.

CASE III.—Julia McG., aged 23, American, married, was admitted to the New York Hospital (service of Dr. Loomis) June 4, 1902. She died 4 hours after admission. On admission the patient was in collapse, and practically moribund. She was cyanosed and bathed in a clammy perspiration. Nose and extremities were cold. Respirations were rapid and somewhat labored. She is a well-nourished woman—face puffy. Mucous membranes and skin are very pale.

Lungs: Just below the angle of the left scapula near the median line there is a small area over which are heard numerous subcrepitant rales without any signs of consolidation. Heart: Action is rapid; not enlarged; no murmurs are heard. Pulse is rapid, regular, fair size, diminished tension. Abdomen is distended and tympanitic. Liver and spleen can not be felt. Cervical glands palpable, discrete, not very hard, size of small marbles. No glands are felt in the axillas or epitrochlear regions. Few small glands in groin. Numerous petechial spots the size of pin heads are seen about the neck, sides of chest, and upper part of abdomen. Temperature is 105.6° ; pulse, 156; respirations, 52.

On the day after her death the following history was obtained from the patient's physician. He recited the facts from memory, but was sure of their accuracy.

He was called to see the patient May 24, and found her complaining of severe pain in the left side, increased on deep inspiration. Temperature was 103° . Respirations about 32. The patient had been taken ill May 23 with a chill, followed by high fever and a stitch in the left side, and rapid breathing. So far as he knows, the patient has always been strong and healthy, and the day before the onset of the illness was apparently in perfect health. She was always rather pale, but strong and well nourished. On May 25, the patient still complained of pain in the left side. Respirations were frequent, and pulse about 120 and feeble. On May 26, an area of dullness was made out over left back with bronchial breathing. On May 29, the signs in the lung had disappeared, but the patient's general condition had not improved. During the 3 previous days she had had a slight hacking cough and a very little sputum, which was not blood-tinged or rusty in color. Her temperature during this time had ranged between 102° and 105° , being lowest in the morning. It continued at about this level up to the time of her admission to the hospital. On May 30, her condition was worse than previously, and the physician noticed several spots on the abdomen, which he describes as "rose-colored." During the night she became delirious. Her general condition continued to grow worse up to time of admission to the hospital. On each of the 3 mornings preceding admission she complained to her physician of having had a slight chill, followed by sweating and symptoms of collapse. On 1 day during her illness the patient had slight diarrhea, but was otherwise constipated. Her spleen was never palpable.

On admission the diagnosis was suggested of a severe infection, probably of either the typhoid bacillus or the streptococcus.

Blood: Hemoglobin, 45%; red blood cells, 2,474,000; leukocytes, 958,000.

Several nucleated red blood cells seen. Widal reaction negative.

DESCRIPTION OF BLOOD.

The red blood-corpuscles stain well, taking a deep orange color in the triacid stain. There is no polychromatophilia and no granular degeneration (methylene-blue). Many corpuscles have become crenated in the process of spreading, but there is practically no poikilocytosis. A few normoblasts and intermediate forms of nucleated red blood cells are seen but no true megaloblasts.

In counting the leukocytes the following classification was adhered to.

1. As small mononuclear cells, are grouped the typical lymphocytes cells, smaller than a red blood-corpuscle and having a very deeply-stained nucleus, some apparently without any cell body, others surrounded by a narrow zone of protoplasm staining faintly pink in the triacid stain. In eosin methylene-blue slides the nuclei stain very deeply, show one or more nucleoli and a rich network of chromatin and a very narrow granular-looking zone of still more deeply staining protoplasm.

2. As polymorphonuclear neutrophiles, are classed the cells with polymorphous nuclei and neutrophilic granular protoplasm. Many of these cells are much smaller than those normally found in the blood—some scarcely as large as a red blood-corpuscle, and in these the neutrophilic granules are remarkably scanty.

3. As myelocytes are grouped the typical large round or oval cells, with oval or indented nuclei eccentrically placed and with profusely granular neutrophilic protoplasm. These vary in size from that of an ordinary polymorphonuclear neutrophile to cells twice that size, the large form predominating. Many of the nuclei have a definite bean shape, and some are so large that they almost fill completely the cell body, leaving only a small area of granular protoplasm visible at the indentation.

4. As eosinophiles, are grouped the polymorphonuclear and mononuclear form. Some of these are very large and are typical eosinophilic myelocytes.

5. All the remaining cells representing numerous varieties are grouped in this class, and they give the blood a truly polymorphous appearance.

(a) Triacid stain: The prevailing leukocyte is an irregularly round mononuclear cell, staining very faintly, and from 2 to 3 times the size of a red blood-corpuscle. The nucleus is round or oval, stains a very pale green, and in most instances nearly fills the cell body. It is usually centrally placed, but many of the oval forms lie to one side. Some of the nuclei contain from 1 to 3 small unstained areas resembling vacuoles. About some of the nuclei is seen a very narrow halo of unstained protoplasm. The cell body stains a very pale pink, and is in most instances fairly definitely outlined. Occasionally it stains more deeply, taking on a lilac tint and having a

stippled appearance, and in some of the cells there are neutrophilic granules, staining so faintly and so few in number that one hesitates to call them true myelocytes. The smaller cells tend to stain more deeply. Some are small round cells only a little larger than a red blood-corpusele, but their nuclei stain not so deeply as in the lymphocytes, and are surrounded by a more abundant cell protoplasm. In the cells of intermediate size the nuclei tend to become irregular, varying from indentations and projections to true polymorphous forms. Some of these cells are identical with the polymorphonuclear neutrophils save in the absence of granules.

(b) Eosin methylene-blue stain: The nuclei of the large cells stain pale blue and look vesicular, but have a fine mesh-work of chromatin fibrils running through them. The protoplasm stains more deeply than the nucleus, varying in color from a deep blue to a paler blue, mixed with a distinct tint of eosin. No basophilic granules seen in any of the cells. No mitotic figures observed.

EPICRISIS.

Fraenkel, in 1895, reported under the heading of acute leukemia, 10 cases, which he had observed, and drew particular attention to the blood picture which he considered typical for such cases, and in itself sufficient to establish the diagnosis. He describes the predominating cell as varying greatly in size from that of a red blood-corpusele to those twice as large and showing every

acute symptoms can be very conveniently accounted for by the portal thrombosis. Two cases of Jewett and another of Bloch and Hirschfeld are certainly more nearly related to von Jaksch's infantile anemia, although both authors prefer to consider them cases of leukemia. Green reports 2 cases in sisters, the first being in all probability true leukemia, but the second case which results in recovery is too imperfectly reported to be identified. Cases preceded by a severe anemia (Litten, Senator, Kormoczi, Gottlieb) and cases presenting the clinical features of Hodgkin's disease, terminating with a blood picture of leukemia (Fleischer and Penzoldt, Mosler, Martin and Mathewson) have also been excluded. The relation of such cases to leukemia has given rise to very interesting discussions and suggestions which cannot be rehearsed here, but until their position is more distinctly determined, it is advisable to exclude them from the list of leukemia.

This revision leaves 111 cases to be considered, and these have been divided into the following groups: 1. Cases in which the blood picture corresponds to that formulated by Fraenkel, 57. 2. Cases in which the small lymphoid cell (the typical lymphocyte) is the predomi-

grade of transition between the two. The large cells contain voluminous nuclei which nearly fill the cell, leaving only a narrow zone of protoplasm about them. The nuclei are usually round or oval, but many show indentations, and some are even polymorphous. The typical small lymphocytes are much less numerous than these large elements, but are still absolutely increased above the normal. He notes further the absence of myelocytes and eosinophiles and the relative and even absolute decrease in the number of polymorphonuclear neutrophils.

Since the report of the first case of acute leukemia by Friedreich, in 1857, I have been able to collect 124 cases reported in the literature before July 1, 1903. In this list I have not included cases reported as acute Hodgkin's disease, even when associated with a high leukocyte count (Franssa-Dreschfeld). It is very probable that such cases belong more properly to the group of acute leukemia, and they are so included by Fussell, Jopson and Taylor, but the blood description is so meager that I have hesitated to admit them. Other cases included in the number above given I think it advisable to omit. Waldstein's case was associated with a chloroma. In Eichhorst's case all of the

nating element, 12. 3. Cases in which the blood description is too meager to allow of any classification, 35. 4. Cases with a very irregular blood picture, 7.

Of the 57 cases in the first group the relative proportion of the leukocytes is fairly definitely stated in 18 cases, and from these the accompanying table is constructed.

A synopsis of the blood picture in all 57 cases is as follows: The red blood-corpuseles are usually very much diminished in number, the decrease progressing gradually to the end. Not infrequently they fall below a million (Hirschlaff, Fussell, Jopson and Taylor, Janeway). However, the disease may be well advanced and the leukemic blood condition established while the red cells are only slightly diminished (Bauer, Bromwell, Brandenburg, Gilbert, and Weil). The hemoglobin is relatively more diminished than the red corpuseles, giving them a low *valeur globulaire*. Nucleated red cells are usually present, but only in small numbers. Exceptionally they are more numerous, and as many as 4,615 per cm. have been counted (Fussell, Jopson and Taylor). Normoblasts are always more numerous than megaloblasts, but the latter may be present in small numbers (Janeway, Brandenburg, Fussell, Jopson and

(Taylor). In some of the most typical cases the entire absence of nucleated red cells has been noted (Bradford and Shaw, Gilbert and Weil).

The number of leukocytes is usually not excessive, and falls generally below 200,000 per cm. The lowest counts, excluding cases associated with an infection, are 20,000 (Denning) and 22,000 (Gilbert and Weil). Some of the highest are 700,000 (Hindenburger), 790,000 (Bradford and Shaw), and 958,000 (Hamman). The cells characteristic of this blood condition varying in size from a red blood-corpuscle to the largest myelocyte have been described. The large forms predominate, but even the small cells may be distinguished from the typical lymphocytes by their more vesicular nuclei and more abundant cell protoplasm, which has a tendency to take more or less deeply the acid dye (Reed). The nuclei in the large forms may be indented or even polymorphous (Fraenkel, Bauer, Rosenblath, Reed). All transition forms from the small to the large cells can be traced and in many instances there is an apparent transition of the large cells to myelocytes (Rosenblath, Hamman, also Simon). Nuclear figures have been frequently observed in the large cells (Fraenkel, Obrastzow).

The polymorphonuclear neutrophils are proportionally very much diminished, and often even absolutely (Fraenkel, Reed, Bradford and Shaw, Bauer, etc.). They are often deficient in neutrophilic granules (Fussel, Jopson and Taylor, Hamman). Their entire absence is reported by Kauert. The eosinophiles, while present in most cases, are generally extremely few. In many cases they are entirely absent (Fraenkel, Bradley, Denning, etc.), and the highest percentage given is 2% (Brandenburg). Myelocytes are also generally present, but in small numbers. They are often absent (Fraenkel, Bauer, Denning, Reed, etc.). The highest percentage present in any case was 5.54% (Fussel, Jopson and Taylor). The small lymphocytes are usually present in numbers absolutely greater than normal, but are relatively much diminished. Their percentage varies very greatly. Mastzellen have been observed in none of the cases.

There has been considerable discussion as to the proper position of the large lymphoid cells, described in the list of leukocytes. Fraenkel while ranking them as lymphatic cells thinks they may come in part from the bone marrow. It was following the sharp distinction drawn by Ehrlich between the marrow cells and the lymph-gland cells that they became universally placed in the latter class and were considered derivatives of the small lymphocyte. Their occurrence in the bone marrow was considered an invasion. These views have been severely contested in the past few years. Not only can we entrench ourselves more obstinately than before behind the assertion of Neuman that it still remains to be shown that the leukemic process has in a single instance spared the bone marrow, but very valuable positive evidence has been furnished in the light of certain cases of lymphatic leukemia in which postmortem there was found no enlargement of the lymphatic glands and no evidence microscopically of any unusual activity on their part, while the marrow showed the characteristic cells in great abundance. (Pappenheim, Walz, Reed). The possibility of such an occurrence forerun the fact when Nageli and Benda demonstrated the presence of both the large and small lymphoid cells in normal bone marrow. Benda calls these cells myelogonion and Nageli myeloblasts, both of which terms imply their view as to their destiny. In a study of experimental leukocytosis Rubenstein found that the first change in the marrow after a discharge of the leukocytes into the blood was a great increase in large homogeneous mononuclear cells which are normally present in small number. After the leukocytosis has persisted for some time there is a marked rise in the percentage of myelocytes. He considers these large lymphoid cells the forerunners of myelocytes and derives them in turn from a smaller lymphoid cell—the mother

cell. These large lymphoid cells found in the marrow have morphologic analogs in Flechsig's Keimcentrum of the lymph glands and the attempts of Nageli and Rubenstein to separate them by staining characteristics do not bear confirmation (Michaelis). To separate the two Benda proposed for the gland cells the term lymphogonion. Wolf has gone a step further and links the two functionally as well as morphologically. His views are very attractive. In early embryonic life the blood cell is a large mononuclear lymphoid cell similar to the one found in the lymph glands, spleen, bone marrow and leukemic blood in the adult. This cell wherever found he classes as the indifferent lymphoid cell—differentiable but its destiny depending on environment. In postembryonic life the hemopoietic organs become differentiated so that there is a division of labor, the marrow being concerned in the production of granulocytes, the lymph glands of lymphocytes and the spleen being concerned principally in phagocytosis. Each of these organs however, retains the indifferent lymphoid cell from which the mature cells are produced and under some circumstances may functionate vicariously. It has been shown in animals that the spleen may take on a myeloid function and such an activity of the spleen has been observed in man. Fraenkel reports having found myelocytes in the glands in a case of scarlet fever and there is now evidence enough that typical lymphocytes may come from the marrow (Pappenheim). Wolf constructs the following scheme:¹

It would seem from such evidence that the large lymphoid cells present in the blood in leukemia come in all cases from the bone marrow, and indeed that they bear as close a relation to the myelocytes as to the typical lymphocytes. The term lymphoid is used advisedly, as it has a morphologic significance alone and no reference to their origin or destiny.

In the absence of any definite pathologic basis our only means of classifying leukemias is according to the blood picture. Ehrlich was the first to adopt this method, but he uses the blood picture merely as a gauge to certain anatomic seats of the disease. Evidence being in favor of the absence of such an indication, it has been proposed to replace the terms myelogenous and lymphatic by the more uncompromising ones, myelocytic and lymphocytic, which have reference to the blood picture alone. It appears, however, unjust from the evidence at hand to relegate a blood picture as distinctive as that of Fraenkel to a sub-group under the lymphocytic variety. It is as characteristic and the clinical symptoms accompanying it as definite as in either of the chronic leukemias. As Naunyn suggested many years ago, and as Wolf more earnestly urges, we must recognize 3 classes of leukemia, between which exist every grade of transition. For the third class he proposes the name lymphoid-cell leukemia.²

The most important clinical characteristic of cases having the blood picture of Fraenkel is acuteness. I have been able to find only four instances in the literature in which this blood type is said to have been associated with a chronic course. Hirschlaff's case is the

¹ Pappenheim will not allow that the lymphoid cell described by Wolf is the starting cell of leukocytic development. He insists that these cells show azurophilic granules and are to be grouped with the large mononuclear leukocytes and cannot be held to develop into strongly basophilic lymphocytes on the one hand and basophilic, neutrophilic, eosinophilic leukocytes and myelocytes on the other. In his scheme the large lymphocyte is the mother cell.

² Pappenheim recognizes only two forms of leukemia—the lymphocytic and the mixed-cell varieties, and opposes the introduction of the lymphoid cell type with very ingenious arguments. His explanation of the intermediate and transition forms is purely hypothetical, and whether leukemia be a single nosologic entity or a group of various pathologic processes, it is an advantage clinically to recognize the three classic blood pictures, each associated with a distinct clinical course.

most important, as the patient, a woman of 58, maintained a great increase in the large mononuclear non-granular cells for 4 years. Grawitz speaks of a very similar case in his book on the blood, and Lenhartz after reporting 4 cases of acute leukemia with Fraenkel's blood picture, before the "Aerztlichen Verein," Hamburg, demonstrated slides made from the blood in a chronic case showing the same condition. Rosenblath reports the case of a woman, aged 32, who died after an illness of about 8 months. The blood taken toward the end of the disease showed 900,000 red cells and 40,000 leukocytes, of which the majority were large mononuclear nongranular cells. It may be suggested that the occurrence of this blood picture was associated with the aggravated symptoms, which led rapidly to death, but such an explanation cannot cover the cases of Grawitz and Hirschlaff. A case reported by Palleri is unique, as it seems to represent a transient occurrence of this blood picture in the course of a chronic leukemia. A patient, who had been ill for some time, came under observation after the onset of fever and hemorrhagic tendencies. The large mononuclear lymphoid cell was the predominating white blood element, but under the administration of arsenic the polymorphonuclear leukocytes became very abundant and the "cure" had continued at the end of several months.

It is a more difficult problem to decide whether a blood picture as found ordinarily in chronic leukemia may be associated with an acute clinical course. Of the 11 cases referred to in which the small lymphocyte was the predominating cell, those of Pappenheim and Cabot alone can be accepted as presenting the typical picture of lymphocytic leukemia. Zumpe, Craig, and Rieder give no further description of the blood than that the prevailing cell was the small lymphocyte, and it is possible that Rieder may have been dealing with a chronic case, for although marked symptoms lasted only 7 weeks, the patient had had enlarged glands and swelling of the abdomen for some time before their onset. The cases of Herrick, Theodor, McCrae, Mixa and Walz seem to represent blood pictures intermediate between the lymphocytic and lymphoid-cell types. Of 1,000 leukocytes counted by Herrick, 868 are classed as small lymphocytes, and 121 as large mononuclear forms, but between the two there is every grade of transition. Theodor states that in his case the largest number of cells are small lymphocytes, but there are also present in great number large mononuclear cells with voluminous, poorly-staining nuclei. In McCrae's case the large mononuclear cells amounted to 45% of all the cells in the first count, but the small lymphocytes became much more numerous later. The cases of Mixa and Walz showed beside the typical lymphocytes very many large mononuclear forms. Although we have included the case of Guinan and Jolly in this class there is much reason for considering that the blood picture coincides more closely with Fraenkel's type. They say the principal variety of cell is a leukocyte having the character of those one calls lymphocytes—with this one peculiarity—they exceed in size appreciably these cells as found in normal blood. They add "this is a fact found constantly in parallel cases." No objection can be found to Pappenheim's case in a woman of 35, which ran its course in a little over 6 weeks. The blood showed hemoglobin, 28%; red cells, 1,024,000; leukocytes, 20,000; polymorphonuclear neutrophiles, 1.5%; large lymphocytes, 2.5%; small lymphocytes, 96%; eosinophiles, 0. Many normoblasts. In Cabot's case, the duration of which is not stated, there was 97.9% of small lymphocytes. Perhaps Reiman's case must be admitted beside those of Pappenheim and Cabot, but in the first count he gives, he states that the polymorphonuclear cells predominated. Toward the end of the disease most of the cells are lymphocytes about the size of red blood-corpuscles.

In the literature there are a number of cases of leukemia running an acute course, with a blood picture

resembling more or less the ordinary type of chronic myelocytic leukemia.¹ Thompson and Ewing report the case of a woman, aged 21, who, 7 months after parturition and 6 weeks before admission, was taken ill with severe sore throat, followed by swelling, pain, and redness of the whole right arm. This subsided and she entered the hospital complaining of pain in the abdomen after a fall on the left side. She died 11 days after admission, having had a high temperature and severe vomiting, followed by collapse. Her blood showed hemoglobin, 20%; red cells, 1,290,000. Nucleated red cells were absent on admission, but became gradually quite numerous, and immediately after death normoblasts were abundant, and many megaloblasts present. The leukocytes were estimated to vary between 50,000 and 100,000. The two differential counts were as follows:

	Percent.	Percent.
Mononuclear forms.....	38	17
Myelocytes.....	12	32
Polymorphonuclear neutrophiles.....	55	48
Eosinophiles.....	An occasional cell	3
Mastzellen.....	Absent	Absent

Another case is reported by Hirschfeld and Alexander:

A man of 21 has pain and slight swelling on the outside of the right foot followed in one week by severe toothache. The tooth is drawn and the wound bleeds profusely. Three days later a rapidly spreading ulcer develops on the left lower lip. He enters the hospital on the fourteenth day of his illness and dies on the fifty-ninth day. After admission the swelling on the foot disappears and the ulceration on the lip heals rapidly. In spite of apparent well-being he grows paler and more prostrated. He has considerable toothache necessitating the drawing of 4 apparently healthy teeth. A fresh ulceration commences on the right side of the lip and cheek and with severe swelling of the face and glandular enlargement in the neck and the development of a slight splenic tumor he dies. The observations on the blood are very interesting. On admission there was a moderate grade of secondary anemia, the leukocytes being present in normal numbers, absolutely and relatively. One month after admission the anemia had progressed and a few normoblasts were present. The leukocytes were 30,800 and showed an increase of lymphoid elements and the presence of myelocytes. The differential counts on the 5 days preceding death were as follows:

Polymorphonuclear with neutrophilic granules.....	68.5	75.5	75.5	63.1	73.2
Polymorphonuclear without granules.....		4.7	2.2	1.6	1.1
Large lymphocytes.....	20	13.2	17.4	19.2	16.1
Small lymphocytes.....	4	3.5	3.6	7.4	1.1
Myelocytes.....	5.8	2.9	1.1	8.6	5.0
Eosinophiles and mastzellen absent.....					

It is evident at a glance that neither of these blood pictures correspond very closely to the average type of chronic myelocytic leukemia. The large number of lymphoid elements in both cases, the small number of myelocytes in the second, the absence of mastzellen in both cases and of eosinophiles in the second are the striking points of difference. Simon has shown, however, that even a chronic case of myelocytic leukemia may run its course without eosinophiles or mastzellen. In both of the foregoing cases the autopsy showed the great mass of marrow cells to consist principally of myelocytes, and the mouth ulcer in the second case was made up almost entirely of myelocytes. The autopsy is after all the deciding point and although one might suggest the possibility of an acute infection causing death in a case of chronic leukemia in Thompson's case and of an acute infection suppressing for a time the blood picture in Hirschfeld's case there are no grounds for urging such a view consistently. The most typical case is reported by Grawitz in which of 190,000 leukocytes 60% were myelocytes, 10% eosinophiles, 10% polymorphonuclear neutrophiles, 5% small lymphocytes, and 15% large mononuclear basophiles.

It may be necessary here to refer to an error that has

¹ Since this was written, an article has appeared collecting the cases of reported acute myelocytic leukemia. Billings and Capps. Amer. Jour. Med. Sciences, September, 1903,

got into the literature. Cabot, in an article on acute leukemia abstracts briefly 2 cases previously reported by Obrastzow which Lazarus in his monograph on leukemia (p. 114) erroneously refers to as cases of acute myelogenous leukemia presented by Cabot himself. Probably from this source the mistake has been copied into the literature. It is safe to say that Obrastzow's cases are not myelocytic leukemia and Fraenkel has accepted them as confirmatory of his blood picture. Obrastzow's description of the leukocytes is as follows and was probably made from unstained specimens.

CASE I.—Their diameter is a little larger than a red blood-corpuscle although there are smaller forms. They are for the most part finely granular and enclose a round nucleus.

CASE II.—Their diameter is a little larger than a red blood-corpuscle; there are also present, but in smaller numbers, very large cells (epithelioid) and finally cells of smaller dimensions.

Accepting the suggestions of the intimate relation of the various types of leukemia one is prepared to meet blood pictures intermediate in type between the 3 principal varieties. We have shown how common such mixed blood pictures are between the lymphocytic and lymphoid-cell type and they are equally as striking if not as numerous between the lymphoid-cell and myelocytic variety. The most important case is that of Michaelis.

A woman of 50, is taken ill 10 weeks before admission, with slight cough, a stitch in the side and general malaise. Examination on admission showed a much enlarged spleen. She ran an afebrile course, the general prostration and pallor increasing rapidly and she died 39 days after admission, of edema of the lungs. The blood a few days after admission showed hemoglobin 40%, red cells 3,450,000, leukocytes 16,000.

	Percent.
Lymphocytes connected by transition forms	{ Small 20.0
	{ Large 56.0
Neutrophilic myelocytes	7.2
Neutrophilic polymorphonuclears	16.0
Eosinophiles	0.4
Mastzellen	0.4

The blood picture changed very little during the course of the illness. Arneth describes in detail the blood of a child. A brief abstract of this case follows:

The patient was taken ill 14 days before admission to the hospital with vomiting and general malaise which confined him to the house for 7 days after which he was able again to attend school but became extremely pallid. On the day of admission he had severe epistaxis with pains in the neck, teeth and abdomen. He grew very apathetic and became unconscious on the same day. He regained consciousness after admission, but grew rapidly weaker and died after 4 days. The blood showed the following picture:

Hemoglobin, 10%; red cells, 256,000; leukocytes, 10,600.

	Percent.	Percent.
Lymphocytes	{ Large 4.9	5.8
	{ Small 35.3	22.9
Polymorphonuclears	{ Neutr. 43.9	53
	{ Eosin. 0.2	0.3
Myelocytes	{ Neutr. 13.0	15.1
	{ Eosin. 0.6	0.5
Large mononuclear cells	2.1	2.4

A very large number of nucleated red blood-corpuscles was present, the majority being megaloblasts. Very marked changes in red cells characteristic of severe anemia were noticed.

It must be admitted that the extreme anemia, the extensive changes in the red corpuscles and the low leukocyte count suggest that this case may be more nearly related to the grave anemias than to leukemia. Two more unusual blood pictures are reported by Spencer, and Stewart and Campbell. Spencer's case is in a man of 38, and runs a rapid course with great increase in the leukocytes in the following proportions:

	Percent.
Polymorphonuclear neutrophiles	34
Lymphocytes (of various sizes)	63
Eosinophiles	2.5
Mastzellen	0.25

Numerous nucleated red cells present. It comes nearest to Fraenkel's type, but the large number of polymorphonuclears and the presence of mastzellen is anomalous. The case of Stewart and Campbell, in a

child of 6, ran its course in about 2 months. The blood toward the end of the disease showed:

Hemoglobin, 21%; red cells, 750,000; leukocytes, 40,000.

	Percent.
Lymphocytes (small)	25
Polymorphonuclear neutrophiles	45
Myelocytes	30

The red blood cells showed disproportion in size, but no poikilocytosis. Normoblasts were fairly numerous.

Cases of transition from one type of leukemia to another are reported, but are unusual. Fleischer and Penzoldt examined the blood in a case of chronic leukemia, and found the large mononuclear cells (very probably myelocytes) greatly increased. When the same patient was examined a year later the leukocytes were less numerous and consisted almost entirely of small lymphoid cells. Von der Wey describes the following changes in his case:

On admission in July there were 33.5% of polymorphonuclear leukocytes, 1.9% of eosinophiles, and 66.5% of mononuclear cells, consisting of a small number of lymphocytes, but mostly myelocytes. In August the patient's condition became much worse, and with the onset of hemorrhagic tendencies the blood picture rapidly changed. At the end of August the count was, 3.7% polymorphonuclears, 0.33% eosinophiles, and 96.3% of mononuclear cells, which are now principally lymphoid cells larger than typical lymphocytes, although some myelocytes persist.

It is interesting to note with what frequency the blood picture of lymphoid leukemia occurs toward the end of the course of chloroma. Indeed, the two diseases resemble one another very strikingly, anatomically as well as clinically. The bone marrow is always involved when the blood assumes leukemic characters, and the blood type in all the cases reported with precision corresponds to that described by Fraenkel. Byrom Bramwell reports an interesting case in which the leukocytes numbered only 8,000, but 95% of these were "lymphocytes," and chiefly large forms. Such an observation suggests that the blood picture may be easily overlooked. The subject is fully reviewed by Rosenblath.¹

CONCLUSIONS.

There are 3 types of leukemia, each associated with a typical clinical picture. Between the blood pictures and the clinical pictures there is every grade of transition. Leukemia running an acute course is nearly always associated with the blood picture described by Fraenkel. When the blood picture described by Fraenkel is observed it is almost certain that the case will run an acute course. The presence of either of the other typical blood pictures is an assurance—however, not absolute—that the disease will run a chronic course.

A COMPARATIVE STUDY OF FRACTURES OF THE EXTREMITIES.¹

BY

M. I. WILBERT, PH.M.,

of Philadelphia.

Director of the Radiographic Laboratory at the German Hospital, Philadelphia, Pa

In the introduction to his book on fractures, Stimson says: "A fracture, in the surgical sense of the word, is the breaking of a bone or a cartilage."

If this rather liberal definition of a fracture be accepted as correct, we must recognize as fractures quite a number of injuries that were formerly classed as sprains. This would also agree with the definition of the word sprain as usually accepted.

"A sprain is the violent straining or wrenching of the soft parts surrounding a joint, without dislocation, and without a fracture of the bony structure."

While it is true that so far as a verbal definition goes, there is no possibility here of mistaking the one for the other, this is not so readily done in actual practice, where it not infrequently happens that even an extensive injury to the osseous framework may be, and sometimes is, mistaken for the more simple lesion. That many cases of actual fracture, particularly at or near the articulating portion of the long bones, have gone unrecognized and untreated, is evidenced by the wellknown popular saying that "a sprain is oftentimes worse than a fracture." This saying is well founded on the fact that when a fracture has been diagnosed as a sprain, and treated as such it usually results in an exuberance of callus that almost invariably causes subsequent impairment of function.

Every Röntgen ray operator has, no doubt, had ample opportunity to learn the variety, and also the frequency of these mistaken diagnoses, so that it will not be necessary to go into this phase of the question at greater length at this time. As an additional proof of the correctness of the statement, however, we should like to call attention to the following table of figures comparing our statistics of total fractures with those published by Stimson:

TABLE NO. 1.—GIVING COMPARATIVE FIGURES OF FREQUENCY OF FRACTURES.

	Stimson.	German Hospital.
Head and neck.....	15	7
Trunk.....	11	5
Upper extremity.....	52	57
Lower extremity.....	22	31

It will be noted that there is quite a marked discrepancy between the comparative numbers of fractures of the extremities and fractures of the remaining portions of the body.

While this difference may, to some extent, be due to our own peculiar environment, and to the class of industrial establishments from which many of our patients come, these purely local conditions will not account entirely for the variations in the figures, particularly as these figures have proved fairly constant over a period of now nearly 8 years.

We believe that the difference in frequency of fractures of the extremities is entirely due to the more accurate diagnosis of injuries to the osseous structure that has been made possible by the introduction and systematic use of the Röntgen rays.

One other feature in connection with the statistics emanating from the radiographic laboratory of the German Hospital that we should like to call your attention to, is the fact that they differ from those ordinarily published,

¹ Read at the meeting of the American Röntgen Ray Society, December 9 and 10, 1903.

in making a distinction between a fracture in the shaft of a bone and an injury at or near a joint.

This, we believe, to be justified by the greater relative importance of a fracture at or near a joint, and also by the fact that injuries at a joint, in a large number of cases, involve more than one bone. The recognition and correct diagnosis of joint fractures, therefore, beside being of practical importance to the rational treatment of a patient, is also of considerable interest and of vital importance from an economic point of view.

TABLE NO. 2.—SHOWING COMPARATIVE FREQUENCY OF FRACTURES IN A SERIES OF 2,000 CONSECUTIVE CASES, COMPARED WITH FIGURES QUOTED BY STIMSON, BECK AND OTHERS.

	German Hospital.	Stimson.
Upper extremity:		
Hand.....	12.5	10.0
Wrist.....	25.5	
Arm.....	5.0	22.25
Elbow.....	12.5	
Humerus.....	1.5	10.0
Shoulder.....	7.5	
Scapula.....		1.25
Clavicle.....		19
Total.....	64.5	62.5
Lower extremity:		
Thigh and hip.....	2.5	7.5
Thigh.....	4.5	
Knee.....		2.5
Patella.....		18.5
Leg.....	5.5	
Ankle.....	14.5	
Foot.....	9.0	9.0
Total.....	36	37.5

This table (No. 2) well illustrates the importance of the subject of joint fracture. If any additional argument were needed, it might be found in the comparative frequency of fractures of the carpus. In textbooks on surgery, carpal fractures are usually dismissed in a perfunctory way, with the statement that they are unusual or very rare. In our experience at the German Hospital we found them to be comparatively frequent. In 1,000 consecutive cases that have been reported, no less than 82 had a fracture involving one or more of the carpal bones, making a total of 8.2% of all fractures.

To appreciate the significance of the figures quoted still more, let us consider for a moment the composition and mechanism of a joint.

In its simplest form a joint is composed of 2 or more bones suitably shaped and arranged. The articulating surfaces of these bones are covered with cartilage and protected by or enveloped in a fibrous tissue, which in turn is lined with a delicate secreting membrane. The different bones constituting the joint are held together by ligaments of various kinds, and are acted upon by muscles that are so distributed and attached as to facilitate movement in the required direction. There is a liberal supply of bloodvessels and nerves to furnish nourishment and to control the motion of the various parts. These, on account of the limited space available, are usually in close proximity to or enveloped in the surrounding structures. If we can conjure up a proper picture of any particular joint, realize its wonderful complexity, and its thorough adaptation to the particular purpose for which it is designed or used, we will readily appreciate why a comparatively slight injury may, and will, occasion considerable disarrangement to the normal function of the joint.

In connection with injuries to or near the articulating surface of a bone, too much stress cannot be laid on the caution to be careful in handling the part. Hamilton, in his justly far-famed treatise on fractures, calls attention to this fact, and says that "the rude and reckless handling of a limb may result in serious additional damage that can never afterward be wholly remedied—augmenting the pain and inflammation, and not infre-

quently, no doubt, determining the occurrence of suppuration, gangrene, and death."

In a later paragraph, the same author adds that "the surgeon should not forget that while a patient is under the influence of an anesthetic, violent manipulations are no less liable to rupture bloodvessels and to lacerate other tissues than if employed when the patient is conscious."

Experience will fully justify these statements, made by Hamilton more than 30 years ago, in counterdistinction to the advice given by some later writers, to administer an anesthetic in all cases that do not admit of ready manipulation for making a complete and accurate diagnosis.

The necessity of a complete and accurate diagnosis of an injury will readily be admitted. Some additional suggestions to the value of a correct diagnosis, particularly of injuries about a joint, may be had from Table No. 3, which gives the approximate age at which the various fractures occurred.

TABLE NO. 3.—GIVING THE APPROXIMATE AGE AT WHICH THE INJURY OCCURRED IN A SERIES OF 1,000 CONSECUTIVE CASES OF FRACTURE OF THE EXTREMITIES.

Age	1-10	11-20	21-30	31-40	41-50	51-60	61-70	Over 70
Upper extremity:								
Hand.....	3	30	26	24	11	3	1	
Wrist.....	5	60	59	35	36	32	14	2
Arm.....	8	20	5	6	4	3	1	
Elbow.....	36	33	14	10	13	4	1	2
Humerus.....	1	4	5	4	1			
Shoulder.....	4	7	19	19	9	15	8	4
Lower extremity:								
Thigh and hip.....	1	5	3	1	6	5	4	
Knee.....	3	5	9	7	6	5	2	
Leg.....	9	6	9	10	12	12	2	
Ankle.....	6	24	46	50	27	19	6	1
Foot.....	2	5	38	26	24	7		2
Total.....	78	199	233	192	152	96	39	11

A glance at this table will suggest the fact that nearly one-fourth (23.3%) of all the fractures occurred in persons between the ages of 21 and 30; 43.2% between the ages of 11 and 30. The economic value of these figures will appeal to us more when we stop to think that the average age in this particular number of cases would not be more than 22, and that at this age the computed expectancy of life is at least 40 years.

When we remember that the earning capacity of the average individual depends very materially on the full and complete use of the various joints of the extremities, and that it may be, and usually is seriously impaired by the loss or impairment of this complete use of the joints we begin to realize the value and importance of the Röntgen rays as a diagnostic agent.

TABLE NO. 4.—GIVING THE SEX AND THE SIDE INVOLVED, IN A SERIES OF 1,000 CONSECUTIVE CASES OF FRACTURE OF THE EXTREMITY.

	Sex.		Side.		Total.
	Male.	Female.	Right.	Left.	
Hand.....	88	10	55	43	98
Wrist.....	195	48	118	125	243
Arm.....	38	9	20	27	47
Elbow.....	92	21	48	65	113
Humerus.....	16	3	8	11	19
Shoulder.....	70	15	59	26	85
Thigh and hip.....	20	5	15	10	25
Knee.....	28	9	21	16	37
Leg.....	43	7	27	23	50
Ankle.....	157	22	80	99	179
Foot.....	99	5	64	40	104
Total.....	846	151	515	485	

Table No. 4 has been introduced as offering some additional and interesting data in connection with a study of frequency of fractures of the extremities.

Among other interesting suggestions the marked, and in many respects distinct difference in the number of fractures involving the right as compared to the left

shoulder, will immediately call to mind the more general use that is made of the right shoulder joint in attempts to protect from possible injuries. The marked difference in the number of fractures of the hand or foot occurring in males, as compared to females is, of course, explained by the extra hazard taken by males in many of their occupations, particularly by those engaged in the manufacturing industries in which iron and other heavy metals play an important part.

Another discrepancy, found in the figures given for fractures of the leg and ankle, can also be attributed to conditions more or less closely connected with the occupation of the individual. Aside from these exceptional cases it is rather interesting to note how closely the remaining figures approximate the frequently suggested ratio of 4 males to 1 female.

There is one other feature in connection with fractures of the extremities that should not be lost sight of, this is embodied in a caution found in many textbooks, usually accredited to Nélaton, to examine the remaining joints of the same extremity for additional injuries, as it not infrequently happens that an adjacent joint may be involved. This is particularly applicable in cases of fracture involving the shaft of one of the long bones in which the resulting deformity may, and frequently does, cause considerable disturbance at the adjoining articulating surface.

Fractures are frequently complicated by the deformity from an old injury; for some occult reason patients will rarely call attention to the previous deformity, and even when questioned will deny having had a previous injury until confronted with unmistakable evidence of the presence of an old deformity. These same unrecognized, or unremembered, injuries to or near a joint, not infrequently play a very important part in the subsequent development of diseases of the bones.

Diseases of the joints are usually ascribed to some constitutional taint; there can be no doubt, however, that in a large number of cases they can be directly traced to a more or less extensive bone injury, received at some earlier period.

This, of course, suggests the question as to how many of these diseased joints could have been averted by the recognition of the true nature of, and the proper treatment of, the initial lesion. Without going at all into a discussion of the treatment of fractures, we should like to call attention to the possible damage that may be done, in this direction, by the not uncommon mistake of keeping a joint at rest for an inordinate period of time. The changes that may be brought about in the composition of a joint are of a grave and oftentimes of a serious nature.

The connective tissue that fills up the interspaces of the joint is most likely to be affected, as it is either compressed or unduly relaxed; in the former case it is likely to become dense, and hard, in the latter, it is more likely to fill with fluid, become soft and pulpy, and eventually undergo further changes and ultimately cause more or less interference with motion, complete ankylosis, and possible degenerative changes in the part.

In conclusion, we would like to say that while it must be admitted that the Röntgen rays, even at the present time, will not indicate the exact nature of all of the possible injuries to the extremities, they do, when properly applied, invariably show all serious lesions of the osseous structure and in a number of cases will indicate correctly the nature and extent of the injuries to the soft parts, particularly when this injury involves the denser portions of the tendons.

It is reasonable then for us to assert that precision and exactness of diagnosis, without incurring any additional risk of injuring surrounding tissues, are practically impossible without the use of the Röntgen rays, and that, without a complete and correct diagnosis of an injury, the accompanying treatment must necessarily be entirely a matter of chance.

In this connection we feel satisfied that a more general adoption of the routine use of the Röntgen rays in all cases of possible injury to the osseous structure will do much toward helping the human race onward toward that ultimate, and perhaps ideal, possibility of freedom from grave ills and unnecessary deformities.

FRACTURE-DISLOCATION OF THE SPINE.*

BY

J. SHELTON HORSLEY, M.D.,

of Richmond, Va.

Professor of Principles of Surgery in the Medical College of Virginia;
Surgeon to Memorial Hospital, Richmond, Va.

The history of laminectomy has been one of many vicissitudes. Dating from the seventh century and the time of Paul d'Egine, it has been alternately held in high favor or condemned as worthless. Its present status with many surgeons may be represented by a quotation from Sir Astley Cooper. In 1823 he said:

If you could save one life in ten, aye, one in a hundred by such an operation, it is your duty to attempt it, notwithstanding any objections which some foolish persons may have urged against it. Though I may not live long enough to see the operation frequently performed, I have no doubt that it will be occasionally performed with success. There is no reason why it should not, and he who says it should not be attempted is a blockhead.

Bolton¹ concludes an article on principles of treatment in injuries of the spinal cord as follows:

Cells and fibers of the cord are readily destroyed, and once destroyed, never regenerate. 1. Extradural hemorrhage does not give rise to cord lesions or symptoms, and requires no treatment. 2. Total lesions of the cord are immediate. The lesion is permanent and requires no treatment. 3. In hematomyelia the clot is absorbed, its site persists as a cavity, or is filled by newly-formed tissue; irregularities of the circulation in surrounding positions of the cord adjust themselves. 4. In partial contusion of the cord the lesion results in permanent destruction of cells and fibers. No treatment is available. 5. In open injuries of the cord there are destruction of cells and fibers, and disturbance of circulation. But here active operative interference is indicated to remove foreign bodies, to facilitate disinfection, to prevent more extensive necrosis, and to facilitate drainage.

This view of Bolton's, pessimistic as it seems, was that of perhaps a majority of surgeons at that time, though Victor Horsley and others advocated laminectomy in these cases, and stated that the only danger was from sepsis. The *New York Medical Record*² in an editorial on the subject says:

The present status of these cases of spinal injury seems to be expressed by saying that nothing can be done for those patients who have the symptoms of crush of the cord at any level, while in other patients the advisability of operating must depend upon the apparent requirement of the individual case, with the chances of doing much good at best but dubious.

John C. Munro³ reports 18 cases of laminectomy, and concludes that the operation is nearly hopeless in acute injuries to the upper half of the cord, though it should be done as giving the only chance of cure. Robert Abbe⁴ reports 4 cases of spinal fracture, and advocates operating under cocain. He says if loss of motion and sensation below the injury is instantaneous and complete, recovery is almost hopeless, though he has had a patient with these symptoms who recovered.

Perhaps the most important papers of late in giving a more hopeful view of the influence of laminectomy on spinal injuries are those of A. J. McCosh,⁵ and Harte and Stewart.⁶ McCosh reports 10 cases of trauma to the cord, and of this number 4 patients showed only partial paralysis of the portion of the body below the injury, or else marked improvement within 24 hours after the injury. The remaining 6 cases were severe and were subjected to laminectomy. Four of these patients died and two recovered completely. In one of the patients

*Read at a meeting of the Southern Surgical and Gynecological Association at Atlanta, December 15, 1903.

who recovered the injury was at the fourth cervical vertebra; in the other at the seventh dorsal vertebra. From their histories it seems most probable that without operation all of these 6 patients would have died.

The case reported by Harte and Stewart in a paper read before the American Surgical Association is of great interest as being one of the few cases recorded from thoroughly reliable sources in which the spinal cord regenerated. The cord was severed by a 32-caliber bullet, and complete paralysis followed at once. Operation was performed 3 hours later. After removing the bullet at the seventh and eighth dorsal vertebrae, there was an interval of $\frac{3}{4}$ inch between the segments of the cord. These were approximated with catgut sutures. Sixteen months afterward the patient could voluntarily flex the toes, flex and extend the legs and thighs, and rotate the thighs, and had the sense of touch, temperature, pain, and position all over. She could stand, by partially supporting herself with a hand on the back of a chair. In the discussion, W. L. Estes reported a somewhat similar case in which there were positive evidences of regeneration of the spinal cord.

It is certainly true that every case of fracture-dislocation of the spine does not need operation. There is no hard and fast rule universally applicable to the treatment of any surgical disease, and surely fracture-dislocation of the spine offers no exception. No one should say that all patients ought to be operated upon; it is equally bad policy never to operate on any. As in all other important surgical conditions, judgment should be exercised as to when to operate. The similarity between injuries of the spinal cord and injuries of the brain should be emphasized, as well as the fact that without an operation or a necropsy, no one can always tell when the cord is completely destroyed.

The plan of McCosh seems excellent. He operates in all cases of complete paralysis below the injury unless there is improvement within 24 hours after the injury; when the trauma is especially marked, he operates sooner. He points out that the danger of delay lies in degenerative changes in the spinal cord which set in soon after the injury. Early operation may arrest or at least lessen this degeneration.

Frequently severe injury of the cord may not kill immediately, but it nearly always leaves the patient a permanent invalid. The following 2 cases illustrate this:

CASE I.—A Mexican girl, of 15, was referred by Dr. M. P. Schuster, of El Paso, Texas. I saw her for the first time June 29, 1903. She gave a history of having been healthy previous to the accident; family history was negative. About 2 years ago she fell from a high swing, striking on her buttocks. There was immediate paralysis of her legs, both as to motion and sensation. The bladder and rectum were slightly disturbed. After 6 months some improvement began in motion and sensation, and the bladder and rectum acted normally. When I saw her 2 years after the accident the bodies of 3 lumbar vertebrae were twisted sharply to the right on an axis running through the spinous processes, which were not greatly altered in their position as far as their tips were concerned. The girl was thin and the bodies of these vertebrae were so rotated that the right transverse processes could be distinctly palpated and seemed just beneath the skin. The sacrum was dislocated forward so the last lumbar vertebra was very prominent and immediately beneath the skin. It had a very small spinous process. The bladder was acting normally; there was a tendency to constipation. There was absence of patellar and ankle reflexes in both legs. In the right leg there was complete loss of all sensation (touch, pain, and temperature) below the knee, and there was an area of anesthesia extending up the posterior surface of the thigh to the gluteal fold. In the left leg there was total anesthesia below the knee, excepting a small strip along the inner side of the leg, inner side of foot, and inner side of great toe. In the left thigh the area of anesthesia corresponded to that of the right. There was no movement of either foot. Both legs could be extended and flexed quite readily, but not forcibly. She could not bear any weight on the feet. Over the lower part of the sacrum there was an ulcer that had a tendency to heal, but when one part of it healed it seemed to spread at another point. She could sit comfortably. Both legs and both thighs were much atrophied and she was emaciated, but seemed in tolerably good health. No operation was deemed advisable in the condition in which I saw her.

CASE II.—R. S., of Las Cruces, New Mexico, is an American boy, aged 14. Previous health before accident was good, excepting that he had always been nervous. When about 10 years of age he was thrown from a horse and dragged some distance. Dr. B. E. Lane, of Las Cruces, was sent for. He found his head fixed to one side; it could not be moved in any direction. Closer examination showed there was a dislocation of an upper cervical vertebra, which it was impossible to reduce. There was considerable pain, but no paralysis. He recovered from the immediate effects of the injury in a few weeks, and the following winter went to school. His head remained in the fixed position. About May, 1901, 2 years after the accident, he began to suffer from pains in his body and limbs; after 2 months there was paralysis of some of the muscles of his hands and arms, and an inability to stand on his legs, though there was no complete paralysis. He did not improve, and was referred to me by Dr. Lane in September, 1902. He was excessively emaciated and nervous. The head was firmly fixed in one position; a bony protuberance, probably a displaced portion of the axis, stuck out to the left of the middle line; his legs seemed almost completely paralyzed, both as to motion and sensation; motion was very slight, and only after great effort; there was weak voluntary movement of the thighs. There was weak motion in arms, forearms, and hands. Sensation seemed impaired over his whole body and neck, though existing in various degrees. He could not turn himself in bed. Bladder and bowels acted regularly and normally. A Röntgen ray picture taken at the time showed a forward dislocation of the axis, and a probable fracture of its spinous process and a part of its lamina. No operation was advised. I regret that the circumstances were such that I could not make a more complete and accurate examination of this interesting patient. I

Case 2.—Forward dislocation of the axis with the atlas.

have been unable to hear from him for 6 months, but believe that he is still alive (see cut).

The next 2 cases are instances of a rapidly fatal result following what was symptomatically complete severing of the cord. I have no notes of these 2 cases, and shall have to give them from memory.

CASE III.—A young man, American, aged about 25. He was a lineman for a telephone company. While stretching the wire he fell from a telephone pole and struck on his shoulder, doubling up like a jack-knife. There was immediate complete paralysis of motion and sensation in both legs. The bladder and rectum were completely paralyzed. I saw him for the first time about 4 weeks after the injury. There was a deformity in the lower dorsal vertebrae about the tenth or eleventh. Paralysis was still complete. There was a rise of several degrees of temperature, probably from a large sloughing pressure-sore, covering practically all of the posterior surface of the sacrum. No operation was advised. He died a week later, and I made a postmortem examination of the spinal canal. At the site of deformity there was no trace of a spinal cord. The canal at this point was filled with old blood clots and a semifluid grayish substance.

CASE IV.—A Mexican laborer, aged about 20, having the appearance of previous good health was shot with a load of buck-shot. One struck in the shoulder and one in the spine about the third or fourth dorsal vertebra. There was immediate complete paralysis of both legs and of that portion of the body below the level of the injury. Motion, sensation and the action of the bladder and the rectum were entirely abolished. The patient was referred to me for treatment by his physician, Dr. D. H. Huffaker, and I saw him with Dr. Huffaker a week after the injury. Pressure sores were forming, and in view of his bad condition and the fact that several days had elapsed since the accident, operation was not advised. He died a few days later.

In the following 2 cases operation was performed after symptoms that seemed to indicate a complete destruction of the cord where the spine was injured. The technic followed was that generally recommended, viz., a straight incision over the spinous processes, pushing back the muscles by blunt dissection, biting off the spinous processes and then removing the laminae with a chisel or preferably a rongeur forceps. No plaster cast or other support was used after operation.

CASE V.—L. C., a Mexican laborer, aged 50. Previous health good. On January 31, 1902, he fell from a wagon loaded with hay and struck on the upper part of his back. There was immediate paralysis of sensation and motion in both legs. He was referred to me by Dr. G. Wehrle, of El Paso, Tex. There was complete paralysis of sensation and motion below the injury, bladder and rectum were paralyzed and patella reflex lost. He suffered considerable pain. There was a marked protuberance at the site of the first lumbar vertebra, with a depression immediately above it. Temperature 99.5°; pulse 80. I operated upon him August 1, making a straight 6-inch incision over the spinous processes at the site of the injury. The spinous process of the last dorsal was fractured, and the dorsal spinal column was dislocated forward on the lumbar spinal column, so that the spinal canal of the dorsal vertebrae rested partly on the body of the first lumbar vertebra, thus partially occluding the canal. There was no fracture except that of the spinous process of the last dorsal. The cord had been caught between the last dorsal and the first lumbar as between scissors, but was not completely crushed because the dislocation had not been extensive enough. It was impossible to reduce the dislocation, so the laminae of the twelfth, eleventh, and tenth dorsal vertebrae were removed. This released the cord and removed all pressure from it; the procedure of chiseling and biting away the laminae was quite difficult, owing to the unnatural depth of the wound from the dislocation. It was important to leave no projecting spicule of bone. The dura was opened and the cord found to be somewhat mashed, but much less seriously injured than had been anticipated. A probe introduced under the dura for 2 inches up and then down the canal met no obstruction. Dura was sutured with catgut, and wound closed with small drain. Patient suffered great pain, after recovering from the anesthetic, but showed only slight shock. The following day his temperature rose to 103°, with pulse 129, but it rapidly subsided and by August 4 (3 days after operation) pulse was 88 and temperature 99.2°. Pain continued severe. There was no improvement of paralysis of motion, sensation or bladder. Bowels moved after many enemas. It was impossible to keep him covered, he would even tear his night-shirt off. On August 7 his temperature and pulse rose slightly. He complained of severe pain in the right chest; there was dulness and impaired breathing in the lower lobe of right lung. He rapidly weakened and without his temperature becoming much elevated or pulse going over 100, died rather suddenly on August 9. A postmortem showed the wound in excellent condition, primary union having taken place except at the small drainage point, and no suppuration had occurred there. The cord seemed distinctly softer than it was at the time of operation. The whole of the lower lobe of the right lung and part of the middle lobe were consolidated and showed all signs of pneumonia.

CASE VI.—T. H., a Mexican laborer, aged 19; previous health good. April 15, 1900, he fell about 30 feet from a house, and struck on his back, probably on the upper dorsal region. There was immediate paralysis of motion and sensation in both legs, and complete paralysis of bladder and rectum. Examination showed absence of patella reflexes. There was deformity at the eleventh and twelfth dorsal vertebrae. His condition did not improve and he was referred to me for operation by Dr. M. P. Schuster 4 weeks after the injury. He was operated upon May 17, under chloroform anesthesia. A 10-inch incision was made over the spines of the lower dorsal and upper lumbar vertebrae. The spines and laminae of the eleventh and twelfth dorsal were fractured and some of the fragments driven in. Part of an articular process had also been fractured and driven in the canal. These fragments were removed and the rest of the laminae of the tenth, eleventh and twelfth bit and chiseled away. The cord was almost severed, only a few fibers of its anterior portion remaining. The dura which had been torn was sutured, a probe having previously demonstrated the absence of other obstructions for 2 inches above and below the injured portion of the cord. The wound was closed with silkwormgut, a small catgut drain having been put in. Recovery from immediate effects of operation was rapid. Temperature had been elevated 1° or 2° before operation, but gradually fell, and a week after operation was practically normal. Three weeks after operation his pulse became rapid and weak, going up to 120 with but little temperature, and his general condition seemed to be failing. This continued for 2 weeks, and without special treatment other than ordinary tonics and feeding, he began to improve. Sensation and motion slowly returned, though there was no sign of either for 2 months after operation. The first definite symptom of improvement was his passing urine voluntarily. This occurred 6 weeks after the operation. He had several bed-

sores, none of which was severe, and all showed a tendency to heal. His condition, as represented by the last report I received from him, June 27, 1903, about 3 years after injury is as follows:

Sexual desire was abolished at first but is now normal, having returned in the last few months. The muscles of both thighs appear practically normal. Sensation in both thighs is also satisfactory. The legs have improved but little if any in either motion or sensation. The muscles are atrophied, flabby and without power. Recently a nail has come off a toe on each foot, leaving a raw surface. With some assistance he can stand, and with a great deal of support on each side he can walk. His bladder and rectum act regularly and normally. His general condition now is best expressed by a quotation from a letter of Dr. H. T. Safford, to whom I am indebted for the notes on this case. "The patient is at present in fine physical condition, with the exception of the degree of paralysis which remains and has not shown any marked improvement of late. He is fatter now than before the injury and quite comfortable except for occasional pains he feels in his legs. His present weight must be nearly 200 pounds."

M.R.I.A.,

of Dublin, Ireland.

I believe that every person who has lived actively in this world for the period of 3 years or upward knows the unpleasant feeling of being "very tired." The same exciting cause carried to a further stage leads to the more advanced experience of being "completely done up." In early life these conditions, like those dependent on most of the other ills to which human nature is liable, are comparatively easily recovered from; when adult age has been reached, they become more serious. As the intensity of the struggle for existence in this world is, far too obviously, on the increase—with the increase of the census returns, the broadcast spread of education, and the general advancement of human intelligence—the regulation of the amount of exertion called forth in the exercise of the duties of life, daily becomes a subject of more important consideration. In the present democratic age the dignity of labor is well recognized, and the importance of regulating the capabilities and energies of the human machine can hardly be overestimated.

The evils of excessive physical exertion must have been well known to humanity ever since the expulsion of Adam from Paradise, with the accompanying penalty of having to earn his bread by the sweat of his brow. Those whom fortune has gifted with independence are never likely to know them, except through their own fault or folly. To the laboring classes of all ages and of all nations they have been only too familiar. This is especially true of the tillers of the soil, whose exertions, depending so largely, as they do, on season and on atmospheric changes, are necessarily more irregular and spasmodic. The descendants of Abel are less likely to become acquainted with the ills of overexertion than the unhappy offspring of Cain. On the other hand, the city artisan is far less liable to the evil results of physical overstrain, for he is regularly accustomed to definite hours of employment at some specialized form of labor, to which his muscles have become habitually accustomed; and such labor ultimately tends to become so much of second nature as to make it a necessity. It is among those members of the community who are called upon to perform prolonged and exhausting physical exertion, of some kind, at irregular intervals, and without requisite preliminary training or sufficient supply of properly chosen nutriment, that the mischievous results of

muscular exhaustion are especially likely to display themselves.

I have elsewhere called the attention of nonprofessional readers to "The Value of Exercise," as a necessary factor in the maintenance of health. Its refreshing and exhilarating effects are, almost invariably, fully appreciated by every one physically capable of enjoying it. But like all the other good things which life affords, it must, in order to do good, be partaken of with moderation. The good and the evil of physical exertion were well indicated in classic times by Ovid, whose reputation in the domains of philosophy and poetic mythology is too much overshadowed in modern times by the notoriety of his amatory productions.

Otia corpus alunt, animus quoque pascitur illis;
Immodicus contra carpit utrumque labor.

"Relaxation strengthens the body and invigorates the mind"—this, of course, refers to the rest which follows well-directed physical and mental effort; "while immoderate exertion exhausts both." The object of the present communication is to show the why, the how, and the how far of the exhaustion so induced.

The muscles of the body are the agents of all voluntary exertion. The activity of muscle is shown in the contraction of its fibers. Like all other tissues of the body the muscles are under the control of the nervous system. The will, whose central organ is placed in the cortical layer of the brain, ordinarily governs muscular action. The cells of this layer telephone their orders to the muscles through the connecting threads which are known as the nerves. The ends of the muscles are attached to the bones. Acting under orders, a muscle shows its obedience by contracting, thereby bringing its more movable end nearer to its more fixed one. In this way all our voluntary movements are performed.

As in the case of all the other tissues of the body, muscle derives its nutrition from the blood, which is continuously pumped by the heart through the branching vessels called arteries, to the microscopic tubes called capillaries, which form a dense network throughout every part of the system. Through the thin and leaky walls of the latter the fluid part of the blood is constantly oozing. Like all other animal tissues, muscle possesses the power of abstracting from this fluid the materials which are necessary for its repair, and letting the rest go. Like the other tissues too, and especially the more complex, its molecular constituents are continuously changing; the older material crumbling down, and the new taking its place. On this account a continuous supply of nutritive fluid must be kept flowing around and between its fibers. It is a wellknown physiologic law that every tissue or organ of the body receives a larger supply of blood when in a state of activity than when in a state of rest. When a muscle is in a state of activity the bloodvessels which convey the nutritive fluid to and through its substance are found to be dilated, and the fluid portion of the blood leaks through the capillary walls in increased quantity; the molecular changes within the constituents of the muscle fiber take place with greater rapidity, and the waste products are washed off in larger quantity, to find their way into the general circulation; partly into the capillary bloodvessels by osmosis, and partly into the open mouths of the minute vessels (lymphatics) which are placed in the interstices of all the tissues to receive the impoverished plasma and convey it away, to be poured at last into the large veins. Accordingly, the nutritive changes take place much more rapidly, and on a larger scale, in an active muscle than in a resting one.

Those molecular changes, which are continuously occurring in living muscle, are, like other chemic changes, necessarily accompanied by the production of heat. Complexity of composition and instability of structure are the leading characteristics of the more highly organized tissues of the animal body. In these

the molecular changes proceed more rapidly, and, accordingly, on them more especially depends the maintenance of the "animal heat" to which living bodies owe their characteristic warmth. Now, the muscular tissue is, after the nervous, the most highly organized of the constituent structures of the animal body. And muscle forms so large a proportion of the mass of the body that it is known to physiologists as the great furnace of the animal economy—about four-fifths of the total heat of the system being evolved within its substance. A knowledge of this fact should forcibly impress upon the reader the immense importance of the maintenance of the healthy functional activity of muscle on the general economy of the whole body.

The muscular debris detached during the continuous waste referred to is finally washed out of the system with the watery excretions in the form of urea, and other less important organic compounds; with various soluble salts of simpler composition, carbonic acid, and water. Now, with the increase of muscular action, the amount of these effete products is proportionally increased. Up to a certain point, the system is able to eliminate by the usual process of chemic change. But with overexertion of the muscular system, a point is soon reached, beyond which the waste products begin to accumulate in the circulation and in the tissues. The various phenomena of *fatigue* then begin to manifest themselves. When the quantity of muscular waste becomes so great that it cannot be removed from the system in the usual way by the emunctory organs, the circulating blood and lymph, which—to use a slightly metaphoric expression—had previously been clear, become muddy. When this stage has been reached, the healthy nutrition of the other organs and tissues, all of which derive their pabulum from the blood, can no longer be maintained. This state of things tells with special effect on the nervous centers. Now as every tissue of the animal body is placed under the government of the nerve centers, it necessarily follows that when the nutrition of the latter becomes deranged, the nutritional changes and functional capacities of the whole system are thrown into a general state of anarchy. This is precisely what happens when muscular fatigue is carried to excess.

In the lower part of the brain—at a little distance above its junction with the spinal marrow—are placed centers which regulate the caliber of the bloodvessels and the temperature of the body. The heat-governing center has a threefold function; it regulates the production, the distribution, and the discharge. When the nutrition of the nerve cells of this triple center is healthily maintained, the result is the exquisite adjustment by which the temperature of warm-blooded animals is so uniformly balanced—the contemplation of the phenomena and mechanisms of which opens up one of the wonderlands of physiologic science.

Let us now direct our attention to the phenomena of excessive muscular exertion—such as we see in the exercise of running. In the earlier stage, the respiration and circulation are both accelerated, and before the amount of exercise passes the "salutary dose," the individual simply enjoys a phase of greater intensity of life, without feeling any trace of discomfort, or incurring the slightest danger. In the advanced stage, respiratory distress sets in; the individual experiences a sensation of constricting tightness about the chest; and a feeling of discomfort in the head, which goes on to the development of the appearances of clouds and flashes before the eyes, ringing sounds in the ears, a general bluntness of sensation, and confusion of impressions and ideas. In a still further stage, a sensation of overpowering anguish overspreads the whole system; the head feels as if bound by an iron band; distressing giddiness sets in; "the brain is overcome by a kind of drunkenness," and finally, the individual loses consciousness, and falls in a fainting state. The heart's action is feeble, and syncope

may prove fatal. Recovery will be more or less rapid and complete, according to the previous state of "training."

Some 15 years ago, the febrile phenomena which sometimes follow violent muscular exertion were, for the first time, described and examined at some length by me, under the name of "The Fever of Overexertion." The condition is well known in the remote parts of Ireland. In some districts it is called "the pleurisy," in others, "the surfeit," etc. The reason for its frequent occurrence among farm laborers in the country is not far to seek. They are mostly in bad training, and their diet, even when sufficient in quantity, is seldom well chosen. Spasmodic efforts are likely to be called for in spring and autumn. Such calls specially affect the owners of small farms, whose families depend largely on their personal exertions. A very heavy day's work is not infrequently followed by an attack of high fever. With rest and proper treatment at the start, it rapidly subsides; but, in such cases, the unhappy patient is often too anxious to allow himself time to recover completely before going back to work. He does enough—for some days or weeks—to feed the slow fever. When this occurs, recovery is hardly ever complete. The poor patient lingers some months, perhaps a year or two, and dies. The explanation is, I believe, to be found in the poisoning of the nerve centers by the passing into the general circulation of an excessive quantity of muscular waste. The heat-regulating centers lose their governing power, and the body wastes with slow fever.

Of the local affections which are likely to be produced by excessive exercise, there are many of importance, but space will not permit more than the mere mention of the principal. Hypertrophy and dilation of the heart are among those oftenest spoken of. Aneurysm is often referable to the same cause. The production of hernia is also notably liable to occur in subjects anatomically predisposed. Varicose veins are also said to be often produced in the same way, but this is much more doubtful. Hemoptysis, emphysema, and other lung troubles have often followed violent exertion. Certain deformities of the body—such as lateral curvature of the spine—may follow the ill-restricted use of certain groups of muscles. Permanent lordosis has been observed in an accomplished acrobat. Cerebral or spinal apoplexy sometimes results from violent exertion. Rupture of muscles and fracture of bones is an obvious result of excessive strain.

I have now, perhaps, said enough to indicate to the general reader the principal ill effects which are likely to follow the abuse of physical exercise. The subject is at present a more important one than it has been at any previous period of the world's history; now that the struggle for existence is more intense, and physical exercise is given so prominent a place in the education of youth. The moral lesson to be derived from this study is an obvious one. It is necessary for even those who have been best endowed by Nature with her physical gifts to remember that their overuse may lead to a sudden and permanent breakdown of health. It is still more desirable for the naturally delicate and weakly to remember that the violent exercises and brilliant gymnastic feats which are so easily and so gracefully performed by their athletic companions are not for them to imitate. Ill-advised efforts in such directions would tend to results nearly as deplorable as those which befell the ambitious frog in *Æsop's* familiar fable. The burden should be, so far as possible, suited to the back which bears it,—in physical exercise as in the other duties and callings of life. Every healthy individual can improve the physical, as well as the mental gifts of nature; by judiciously taking to use, without abusing them. While a fair amount of well-regulated muscular exercise is one of the very best agents for retaining and improving a healthy state of both body and mind, indulgence in excessive and ill-arranged feats of muscular exertion is one of the surest ways of permanently impairing their functions.

THE MODERN TREATMENT OF WOUNDS.¹

BY

WALTER LATHROP, M.D.,

of Hazleton, Pa.

Superintendent and Surgeon, State Hospital, Hazleton, Pa., Surgeon,
L. V. R. R.

In these days of asepsis and antisepsis, the treatment of wounds of various kinds, aside from operative incisions, is of sufficient importance to merit our consideration.

Railway surgeons meet most of the wounds classified as contused, lacerated, incised and punctured, while those connected with hospitals, see in addition, stab and gunshot wounds. To treat these various kinds, in the manner best calculated to secure good results, and primary union if possible, should be our aim.

During the past 4 years it has been my privilege to have under my care, directly and indirectly, nearly 2,000 wounds of various kinds, ranging from simple incisions, to severe lacerations, from the cut of a razor to the tearing by teeth in the rollers of a coal-breaker.

In this series of cases there were 1,032 lacerated; 392 incised; 277 infected; 114 stab and punctured, and 102 gunshot wounds.

Lacerated Wounds.—The majority were situated on the hands and fingers, the wounds being caused usually by the hand being caught in machinery, or lacerated by coal or rock. Of these lacerations of the hand there were 412, and I have not included many that required amputation, or partial amputation, as when the injury was caused by the explosion of dualin caps. Next in frequency were scalp wounds, of which there were 366; these were due to a fall of coal or rock, or debris from a blast, or explosion. Following the scalp wounds, there were 93 of the foot; 75 of the face; 28 of the back; 26 of the leg; 11 of the arm; 9 of the thigh, and 2 of the groin.

Incised wounds in order of frequency follow: Scalp, 120 cases; fingers, 70 cases; hand, 47 cases; leg, 31 cases; wrist, 28 cases; face, 16 cases.

Infected Wounds: The initial injury, or wound, was located in the fingers in 115 cases; hand, 87 cases; forearm, 42 cases; scalp, 13 cases; foot, 14 cases, and leg, 6 cases.

Punctured wounds were nearly all located in the sole of the foot, or in the heel. Of these there were, heel or sole, 80 cases; ball of thumb, 9 cases; thigh, 7 cases; calf, 2 cases; back, 2 cases; brain, 1 case.

Stab Wounds: Abdomen, 5 cases; chest, 3 cases; back, 4 cases; brain, 1 case.

Gunshot Wounds: Hand, 26 cases; back, 18 cases; chest, 16 cases; head, 14 cases; foot, 11 cases; buttocks, 9 cases; abdomen, 8 cases.

The majority of wounds which railway surgeons are called upon to treat are of the lacerated variety, and the sooner we get these patients the better are our results, for in no class of wounds, except poisoned wounds, does delay mean more. Many cases of extensive laceration of the soft parts require considerable conservatism, care, and patience in order to restore the injured member to nearly former usefulness, and I have seen parts saved by modern methods that would have required amputation or partial amputation a few years ago.

In treating an ordinary lacerated wound, we should check hemorrhage, and then carefully cleanse the wound and surrounding parts. If too painful, we should etherize the patient, and proceed to do a careful and thorough cleaning; all foreign bodies, such as coal dirt, splinters, etc., are removed. I prefer formaldehyd soap, 10%, to begin with, followed by mercuric chlorid solution and sterile water. The lacerated skin is next trimmed where necessary, and the wound converted into an incised one as nearly as possible. Any severed tendons are united, the edges carefully sutured, and the injured member dressed with the usual sterile gauze and cotton—a dusting powder may be used if deemed advisable. A splint may be applied when immobility is desired, and it is often a most excellent procedure. The dressings should not be removed for several days, unless rise of temperature gives warning that sloughing or infection is taking place. When the laceration is very extensive, and we expect considerable oozing, and probable sloughing, we should provide for drainage, by tube

¹ Read before New York State Association of Railway Surgeons, Academy of Medicine New York City, November 12, 1903.

or gauze; my preference is for strips of gauze, either sterile, or iodoform 5%. The subsequent treatment is familiar to all, and needs no mention other than thorough irrigation when the dressings are changed, if drainage is used. In my experience, many incised wounds have been due to brawls, in which bottles and knives have been used, while others have been caused by a fall of sharp bony coal or rock; or falling on or through glass, and by injury in factories. Wounds of this class have usually clean-cut edges, and may be very deep or only superficial. The preliminary care or preparation is very essential, for in these cases we should get primary union if our aseptic procedure is thorough. These wounds, unless very extensive, are sutured carefully, and then sealed with gauze and collodion; cotton and bandage may or may not be applied, at the discretion of the surgeon. Nearly all scalp wounds of this character may be sealed up, and no further trouble experienced. As before stated, thorough asepsis is the keynote of success.

The subject of infection is of great importance, and in this class of wounds, if properly treated, we have an opportunity to achieve considerable success. In my locality we see a great many of these cases among the foreign element, and often, I am sorry to say, among intelligent Americans, who have attempted home cures by some old-fashioned remedy. A miner will cut his finger or hand with a piece of coal or a piece of rusty iron, then take his quid of tobacco from his mouth, plaster it over the wound, and tie a rag around it till he gets home, or sees a doctor, or he will put leaves or salve on it and wait for developments. The injured part usually begins to get sore, and on the advice of some friend and alas, at times a physician, he will apply a flaxseed poultice, and then the trouble begins, ending with a diffuse cellulitis, a localized abscess, or a bad case of septicemia.

I believe the injudicious use of poultices is the cause of more cases of infected wounds, abscesses, diffuse cellulitis, and septicemia than any other agent, except direct infection. I have not ordered or used a flaxseed poultice in a long time, and hope never to use one surgically. They are hotbeds of infection, germ-breeders, and relics of preantiseptic days. Nicholas Senn¹ says: "The ordinary filthy poultice of flaxseed, slippery elm, bread and milk, has no longer a place among the resources of the aseptic surgeon. The common poultice is a hotbed for bacteria, and as such should be discarded. In the treatment of an ordinary furuncle with poultices, I am sure that almost every surgeon must have seen occasionally the development of innumerable minute daughter-furuncles in the surface covered by the poultice. In phlegmonous inflammation of the fingers or hand, the prolonged use of the poultice is followed by maceration of the skin, extensive edema of the superficial structures, a flabby condition of the granulations—in fact, all the evidences which point to the poultice as a means of favoring the extension of the infected process." In the early stages of the infection, or cellulitis, the use of cold applications is of great value. It produces a needed contraction of the capillaries, and inhibits to a certain extent the growth of bacteria. The ice bag is a most useful means of applying cold, and by its timely use serious trouble may often be averted, but when the structures are deeply involved and the capillaries are more or less obstructed, it may do harm. My own experience with infected wounds and pus has convinced me that incision and drainage is the *sine qua non* of success.

The one great agent in combating infection, either preventing it when suspected, or checking its course when started, is carbolic acid, and I am a firm believer in most of the teachings of Powell in regard to the use of this drug. In dispensary work we have many cases

of infected wounds, the patients appearing for treatment from 1 to 10 days after the wound was received. If no pus is present, the wound is cleaned and thoroughly swabbed with the acid (usually a dram to the ounce), or if not severe, a 5% solution is used; the wound is then dressed, usually with a wet gauze, $\frac{1}{10}$ carbolic, and the patient told to report in 24 hours, when we usually find a healthy surface, which can be dressed dry and heals rapidly, or in many instances, sutures can be inserted, and a better scar obtained. If suppuration is present and extending up the hand or forearm, the patient is etherized, a free incision made, the pus evacuated, and wiped dry; hydrogen dioxid is freely used, followed by sterile water, or normal salt solution (sterile), and after this the entire cavity is carefully mopped with pure carbolic acid, care being taken to get it in contact with every part that is infected. The cavity and surface is then washed with alcohol, and the usual dressings applied, drainage being inserted if deemed necessary. These patients, as a rule, all do well, and the spread of infection is almost certain to be checked. If you have not tried this method, take the first opportunity that presents itself, and watch the results. My assistant, Dr. H. S. Ballard, was a great sceptic on the subject of infected wounds, but after an honest and thorough trial in a large number of cases, he is now an enthusiast and a convert to carbolic acid.

It may be well to remark that in cases seen late, and in which the septic process has invaded the system, the use of antistreptococcus serum is very valuable. It should be given in full dose, 10 cc., and repeated once or twice in 24 hours, unless the condition improves. I have used it in a number of bad cases, with excellent results, and also had 3 injections myself, during a severe attack of blood-poisoning contracted while operating on a septic patient. In regard to stab and punctured wounds the treatment is usually very clear. First, stab wounds, in most instances, are caused by a stiletto, used by men who understand how to cut, and the great danger and frequently fatal results are due to the fact that when the blade is driven into a victim, the instrument is quickly turned and made to cut in various directions with great rapidity; it is then withdrawn, and only a small valve-like opening is seen, looking like a trivial wound. By those who have had experience with these cases they are approached with the expectation of severe internal hemorrhage, probably injury of viscera, with frequently a fatal outcome. The patient, as a rule, should be promptly anesthetized, the wound enlarged, and thorough exploration made, under rigid asepsis, and the damage repaired so far as possible. Shock is frequently very marked, and when present you may be sure of internal bleeding and probable injury of the viscera. Some months ago there was brought to the hospital a young man who had been stabbed in the right groin by an Italian. The wound of entrance was about $\frac{1}{2}$ inch long, and shock was severe. He was rapidly prepared for operation, and a laparotomy performed; we found the intestine nearly severed, mesenteric vessels cut, and the bladder opened fully an inch. Considerable time had elapsed between the infliction of the wound, and his coming to the hospital. He lived 48 hours. I mention this case to illustrate how stab wounds can do so much damage. Drainage should be the rule in these cases.

The usual punctured wound is made by some blunt instrument, generally a nail, and the foot is the most frequent location of these injuries. The entrance closes like a valve, while any foreign substance is buried in the deeper tissue. These wounds should be freely opened to the bottom and cleansed, after which a solution of a dram to the ounce carbolic is used, and the wound dressed. Drainage is of value, though rarely necessary if the case is seen soon after the injury. I have had 1 case of tetanus due to a rusty nail penetrating the foot; flaxseed poultices were freely used, and 5 days after the

¹ Principles of Surgery, p. 122.

injury the patient was brought to the hospital with symptoms of tetanus, which rapidly increased, and he died 2 days later. In regard to gunshot wounds, so much has been written upon the subject by able men that it would be superfluous to dwell at any length on their treatment. In the community where I live strikes have been of frequent occurrence, and the gunshot cases have been quite numerous. The only rational treatment of bullet wounds of the abdomen is immediate laparotomy. The last patient I had was shot near the umbilicus, and I found 9 perforations of the gut; the man was operated upon in less than 2 hours from the time he was shot. He recovered and appeared in court later on. I mention this case to show the benefit of early interference. In gunshot wounds of the extremities, the Röntgen ray is of great help in locating the bullet, and makes its removal easy. In wounds of the chest, provide drainage and wait for nature to cure, unless you have clear and urgent reasons for operating. Most of these patients recover; at least, that has been my experience in more than a dozen instances. The same is true of bullet wounds of the skull and brain—provide free drainage by enlargement of wound, and remove all spicules of bone; rigid asepsis is essential to prevent infection.

I would emphasize the efficacy of carbolic acid in the prevention of infection in wounds, and its extension in those already infected.

SPECIAL ARTICLES

A BACTERIOLOGICAL STUDY OF THE INTESTINES OF FISH.¹

BY

EDITH LOEBER, A.B.,
of New Orleans, La.

The bacteriologic examinations of water that have been reported do not seem to take into account the influence, if any, of the fauna of these waters on their bacterial contents. The significance of the bacterial flora of the intestines of fish has received very little attention. The fact that their digestive tracts might furnish a place for the multiplication of certain species, which would be given off to the water, does not seem to have received any special attention. It seems very desirable to determine the species of bacteria normally existing in the digestive tract of fish, not merely those in the contents, and which must be considered of transitory duration and which will vary from time to time with the food and the extent of the contamination of the water, but also those that have become more permanently localized in the mucosa. It is also a matter of more than general interest to determine whether *B. coli communis*, which is found so constantly in the digestive tract of mammalia and fowls, is also present in these cold-blooded creatures.

The immediate objects of this investigation, therefore, were to determine, (1) the bacteria that have become localized, and to that extent parasitic, in the intestinal mucosa of fish, together with their distribution on the mucosa, and (2) to determine the relation existing between these bacteria and those present in the feces.

Source of Material.—The fish examined were medium-sized perch, suckers, and bass obtained from Cayuga Lake and two of its tributaries (Fall Creek and Six Mile Creek). Cayuga Lake receives the sewage of Ithaca, and Fall and Six Mile Creeks, the drainage of several small hamlets.

Some of the fish were obtained and examined during October and November, 1902, and the others in March, April, and May of this year (1903). This divides the subject matter of this article practically into two parts. The fish, in most instances, were alive when received at the laboratory. They were killed,

washed, and placed in a sterile pan. With aseptic instruments a median abdominal incision was made exposing the viscera. The alimentary canal was then carefully dissected and transferred to a sterilized vessel. The intestine was opened from gullet to anus, the feces removed, leaving the mucosa practically free from intestinal contents. The mucosa was gently scraped with a sterile knife, and tubes of bouillon were inoculated with an oese of the scrapings from the duodenum, ileum, and colon. The tubes were placed in an incubator at 37° C. for 24 hours, and gelatin and agar plates were made with an oese of bouillon from each of the tubes.

After 36 hours the plates were examined for the purpose of identifying species irrespective of the number of colonies. This method was followed in the examination of a few fish. In two instances the entire intestine was placed in a flask of bouillon grown in the incubator, and subsequently several series of

plates were made from the flasks. With the larger number of fish, however, plate cultures in agar and gelatin were made directly from mucosa and the number of colonies and the species were determined for each individual. The results of these examinations showed that the following organisms were present: *B. proteus vulgaris*, *B. fluorescens liquefaciens*, *B. mesentericus*, and *B. zopfi*. *B. proteus vulgaris* was the predominating organism. It appeared in some of the plates in almost pure culture.

The fish obtained in the spring were treated in the same manner as those first examined with the exceptions that after removing the feces, the mucosa was thoroughly washed with sterile water, then scraped, and the scrapings from each of the three portions (heretofore mentioned) of the intestines were directly inoculated into liquid agar and gelatin with which plates were made. Each plate contained an oese of the fresh material.

¹ This work was done in the Bacteriologic Laboratory of the Medical Department, Cornell University, Ithaca, N. Y.

After 21 hours' growth in the incubator the colonies on the agar plates were carefully examined and counted and the species carefully determined. Subsequent examinations of cultures did not show appreciable change in numbers of colonies or the addition of new species. In all cases tubes of bouillon were inoculated. These gave very vigorous growths. In most cases the colonies on the gelatin plates were more numerous than those on the agar plates after a period of from 3 to 4 days. The tendency to liquefaction, however, rendered it impossible to determine the exact number of colonies. The appended table contains the number of colonies obtained from each portion of the intestines when a single oese of its mucosa scrapings was used.

The species identified were *B. proteus vulgaris*, *B. proteus zenkeri*, *B. subtilis*, *B. mesentericus*, *B. fluorescens liquefaciens*, and *B. lactis aerogenes*. A few fungi were also present. *B. proteus vulgaris* was present in the colon of every fish, in the duodenum of all but two, and in the ileum of all but one. *B. fluorescens liquefaciens* appeared in small numbers and *B. mesentericus* in relatively large numbers. *B. proteus vulgaris* predominated.

As observed in the table, the number of bacteria in the feces was very large in every instance examined. *B. lactis aerogenes* and *B. subtilis* seemed to be the organisms predominating in the feces, although *B. proteus* also appeared. The *subtilis* bacillus in one instance was demonstrated in the mucosa of all three portions of the alimentary tract as well as in the feces. *B. lactis aerogenes* only appeared in very small numbers, and in but a few fish. As a rule, the bacteria in the feces corresponded to those most commonly found in the water, while those present in the mucosa were not those appearing in large numbers in the water, as determined by examinations heretofore made in this laboratory.

In conclusion, I would state that from the findings of the examinations thus far made, it appears that in the fish taken from Cayuga Lake, Fall and Six Mile Creeks, *B. proteus vulgaris* is a normal inhabitant of the mucosa of the alimentary tract (duodenum, ileum, and colon), but especially in the colon. As a rule, this organism was the predominating form. It is of special interest to note that *B. coli communis* was not found in a single instance in these examinations.

In closing, I desire to acknowledge my indebtedness to Dr. V. A. Moore for helpful suggestions and valuable assistance, which have materially aided in this investigation.

Mortality in Chicago.—The Bulletin of the Chicago Health Department for the week ended January 2, says: "Including the 587 theater fire deaths, accounted for by the Coroner's office and the Police Department, but not yet reported at the close of the year to the Bureau of Vital Statistics of the Department, the total deaths for 1903 will number 28,940 instead of the 28,353 given in the appended Statement of Mortality for the year. This will increase the deathrate from 15.04 per 1,000 to 15.35 per 1,000. Deaths from violence were already more than 12% in excess of the average for the period since the census year 1900; but these 587 theater deaths swell the excess to 41.5% over the yearly average of violent deaths. Even with this addition to the total mortality the deathrate is 6% lower than the yearly average since 1892, although it is 8.2% higher than that of 1901, and 5.3% higher than that of 1902."

Severer Examination for Pharmacists.—The State Pharmaceutical Board will hold a more severe examination for applicants to practise pharmacy, at the examination, January 16, than previously. Heretofore the examination has been a written one only, but this year all those applying for a regular pharmacist certificate will have to undergo a laboratory examination as well as a written one. This will be the first time this examination has been given. Those applying for a qualified assistant certificate will be asked to pass the written examination only, as the laboratory test only applies to prescription clerks and pharmacists. There were many applicants in former years who had the practical ideas but were unable to express them in a theoretic manner. The board will determine by the average attained in each of the examinations. Formerly examinations were held at Pittsburg and Philadelphia and 2 members of the board were present in Pittsburg and the other 3 were present at Philadelphia. In the January examination all the members of the board will be present at Philadelphia, there being no other examination. The board requests all applications to be sent to Secretary Charles T. George, at Harrisburg, 10 days before the examinations are held.

5.—**The Dental Pulp.**—T. E. Constant describes the macroscopic embryologic appearances of the pulp with the surrounding alveolar crypts. Contrary to description, in the 9 months' fetus and at birth the crypts are entirely closed. The roof is very thin, although complete before the bony septa between the various teeth. He does not accept any of the current theories as to the cause of the eruption of the teeth, but believes this process is due to the mechanical force of blood-pressure. The pulp forms a fleshy column of vascular tissue on which the crown rests. Under the calcifying margins of the crown is the pad of tissue which forms the junction of the sac and pulp and between the crown and walls of the crypt is the vascular tooth sac which is injected from the same source as the pulp. Above the crown is the mucous membrane and submucous tissue. Thus it is obvious that the blood-pressure exerted in the pulp acts at mechanical advantage in comparison with the pressure in tissues overlying the crown and thus blood-pressure makes room for the developing root in the direction of least resistance. That the pulps exercise a trophic influence on the alveolar process is shown in the case of unopposed teeth. When the pulp is dead, elongation is unaccompanied by any down or up growth of the alveolar ridge, whereas in the case of living teeth this ridge is deepened. Another trophic function is the pulp's influence on resorption of the roots of the temporary teeth. When the pulp has been destroyed absorption is much slower and this is one reason we find the apices of the roots protruding and causing ulceration of the mucous membrane, they having been deflected by the advancing crown of the permanent successor. [H.M.]

9.—**Medical Trusteeship and a Central Laboratory.**—A. P. Ohlmacher thinks the contact between the medical profession and State medical institutions not close enough. The medical and scientific work in these is not what it should be. There should be at least one progressive medical man on each board who could educate his fellow trustees to the needs of the institution. A central pathologic institute as part of the State hospital system would help to bring the profession into sympathetic relationship with the latter. New York already has one. The initiative in the establishment of such an institute should be taken by the State Medical Association. [H.M.]

5. Mercuric Cyanid as a Surgical Disinfectant. CHARLES HARRINGTON.

1.—Cardiac Displacement.—A. K. Stone reviews the teachings of the Lyons school and adds observations of his own. He describes the mirror heart, in which all the parts are congenitally transposed, but can find no case on record. Dextrocardia seen at autopsies in young infants has practically always been accompanied by malformation of the heart itself, most frequently shown in absence of the ventricular septum. Pericarditis has been found in a 7 months' fetus, and changes in the heart axis may possibly be started by such processes and not be due to real change in the development of the organ. All cases in which the heart points to the right, if there are traces of pleurisy or pericarditis having been present, must be considered as acquired conditions unless proved otherwise by autopsy. The writer presents cases, illustrating how marked dislocation can exist and yet give no symptom, either at the time of its occurrence or later, although the patient may lead a laborious life. While movements due to adhesions, cavities or sclerosed lung tissue with accompanying emphysema are often erratic, those caused by air or fluid in the pleural cavity or by the contraction of one lung in whole or in part are practically subject to certain definite laws. One reason why this has escaped notice is that the heart, if not held by adhesions, will often slip back into its proper position when the chest is open and the pressure within the pleural cavities has been made equal. [H.M.]

2.—Intermittent Hydronephrosis; Uterine Fibroid.—M. H. Richardson makes reference to a case already reported by him, in which he operated upon a patient for intermittent hydronephrosis. A similar case is reported by the author in the present paper. The patient was similarly operated upon, with equally happy results. A third case is reported with a diagnosis of intermittent hydronephrosis, which the author had decided to operate upon, but operation had not been performed at time of writing. The operation which Richardson calls ureteroplasty corresponds in principle to the Heinecke-Mikulicz operation for stricture of the pylorus. The junction of the ureter and the dilated renal pelvis is incised longitudinally, and this longitudinal incision is sewed into a transverse line. The effects of the kink or sharp bend at the origin of the ureter is thereby overcome. Absolute cure followed in both cases. He found this route for exploring the pelvis of the kidney so easy that he has used it a number of times since in preference to the usual one of going through the cortex for renal stone or for other reasons. In the same paper Richardson discusses the danger of malignant degeneration in uterine fibroids. He holds that these should be removed, because the danger of operation in skilled hands is far less than the danger of malignancy. It is only by promptest surgical intervention that malignant tumors of the uterus permit radical cure. Whenever we postpone operation on uterine tumors—no matter how benign these tumors may seem—we are running a risk beside which the dangers of operation are but trivial. The older the patient, of course, the more imperative is exploration, for the tendency to malignancy increases with age, just as, unfortunately, the dangers of operation increase. [A.B.C.]

3.—Cases of Intussusception.—F. G. Balch makes reference to a case of intussusception already reported by him in which 56 inches of necrotic bowel were resected and the patient recovered. In the present paper he reports another case occurring in an infant of 5½ months. The intussusception was of the enteric ileocecal variety; it was reduced by operation and the child recovered. Another case, occurring in an infant of 6 months, was operated upon. An intussusception was found in the ileocecal region, but its exact variety is not noted in the record. Six inches of gangrenous bowel were resected but the patient died 7 hours later. He states that since 1897 there have been 10 cases of intussusception at the Massachusetts General Hospital. One of these was reduced in bringing the child to the hospital, the 9 other cases were operated upon; 3 of the patients were over 21 years of age, 2 of whom recovered. Including the 2 cases reported in this paper and operated upon outside of the hospital it makes a series of 8 cases including the 6 at the Massachusetts General Hospital all occurring in children or infants; out of this number, 5 died. So far as it is possible to draw any conclusion from such a limited number of

cases, it would seem that the mortality decreases rapidly with the age of the patient. In children under 1 year of age intussusception is usually fatal. Very early operation offers the best chance of recovery. [A.B.C.]

4.—The Bicycle as a Therapeutic Agent.—L. H. Gulick recommends the bicycle in cases of depressed vitality with muscular weakness, ill-defined pains in the back and shoulders, inability to sleep satisfactorily, uncertain digestion, and general feeling of worry and depression. Muscular exercise increases vitality by increasing metabolism. The exercise should involve the large muscular masses. The neural expenditure involved to secure the same result is far greater when the muscles are small. When exercise is done with the legs it is done with ease; when with the arms it is accomplished, by women at least, with the greatest difficulty. Trembling of the hands indicates overexpenditure of effort. In bicycle riding the work is done by the large muscles. This explains why it is easier to affect appetite, sleep, circulation, and respiration by this as compared with formal gymnastics. The size of the load, too, is small in comparison with the strength, and the movements are automatic. This also conserves neural outlay. Pleasant psychic associations and fresh air increase the benefit. Success in this treatment depends on the adaptation of the dose to the individual. After 5 minutes' exercise the pulse-rate should be counted. If below 100 the exercise may be continued, if several such periods fail to increase the rate. If above 100 the exercise may be renewed after 5 minutes' rest, if in the interval the beats have gone down to 70 or 80. If consciousness of fatigue continues over night, too much exercise has been taken. [H.M.]

5.—Mercuric Cyanid as a Surgical Disinfectant.—Charles Harrington has experimented with solutions of varying strength of mercuric cyanid to determine its efficacy in surgical practice. It has been claimed that in 1-1,000 and 1-2,000 solutions it is a good substitute for mercuric chlorid over which it is claimed to possess the advantage that it does not precipitate albumins and it is rapid in action. His tests consisted in placing silk threads impregnated with 24-hour old bouillon cultures of *Bacillus pyocyaneus*, *Bacillus coli communis*, *Staphylococcus pyogenes aureus*, and *albus* in a 1-1,000 solution of mercuric cyanid. *Bacillus pyocyaneus* and *Bacillus coli communis* were killed in every instance within 1½ minutes; *Staphylococcus albus* survived exposure up to 25 minutes, but was destroyed in half an hour; *Staphylococcus aureus* was unaffected by contact for no less than 3 hours. Mercuric cyanid in combination with double its weight of borax was likewise tried, with similar results. Harrington says the above results can lead to but one conclusion concerning the practical value of mercuric cyanid, for a substance which, when employed in the strength recommended, cannot destroy all known species of pus organisms within 3 hours, and in double that strength accomplishes nothing in 30 minutes, can hardly be classed among the efficient germicides. [A.B.C.]

Medical Record.

1. The Serum Treatment of Typhoid Fever. MAX EINHORN.
2. The Röntgen or Triultraviolet Rays, their Nature, Application, and Dermatologic Effects. FRANCIS LE ROY SATERLEE, JR.
3. Röntgen Ray Dermatitis as Influenced by Idiosyncrasy. A. D. ROCKWELL.
4. Liquefied Air. A. CAMPBELL WHITE.
5. A Case of Primary Carcinoma of the Lung Diagnosed from the Expectoration. FREDERICK F. C. DEMAREST.

1.—Serum Treatment of Typhoid.—M. Einhorn finds that in most cases the disease does not seem to be materially shortened. Either on the day after the first or the second injection a marked reduction of fever usually occurs; this is about 1° or 2° lower than previous remissions and lasts longer. The general condition, especially the sensory and nervous symptoms are much improved, so that some grave complications, as sleeplessness, headache, restlessness, delirium, disappear nearly entirely. In the cases reported, treatment began from the ninth to the fifteenth day. We may expect better results from earlier injections. They should be given even before diagnosis is certain. There seems to be no danger. A passing erythema

occurred in 2 cases and in 1 chills followed for a quarter to a half hour. [H.M.]

2.—Röntgen Rays: Their Nature, Application, and Dermatologic Effects.—F. L. Satterlee gives a brief history of the discovery of Röntgen rays, notes improvements which have been made to apparatus for developing the rays, and enters into a technical discussion of their nature. Directions are given for the application of the rays clinically. He says a good tube, a Kahibaum screen, and Wappler coil, would make as perfect a Röntgen ray outfit as any operator could desire. A portion of the article is devoted to a consideration of Röntgen ray dermatitis, which, it appears, will inevitably develop in a few susceptible cases, despite any known precautions. Such dermatitis is rebellious, but he has found the following very soothing and beneficial: One part of carbolic acid in 8 parts of rosewater ointment, applied to the inflamed part on retiring. Röntgen rays are not a positive agent for diagnosis. Proof of this is in the fact that radiographs were formerly admitted as evidence in the courts of New York, but are so no longer. Many conditions are cited in which the rays may be used with benefit. Satterlee says it is now 7 years since the Röntgen ray was made known to the world, and in that time its development has gone on almost uninterruptedly. The outcome of which is that thousands of persons are now perfectly well and strong who prior to this time had been suffering from chronic disturbances. Who can tell what the future of such an all-powerful agent is to be? [A.B.C.]

3.—Röntgen Ray Dermatitis as Influenced by Idiosyncrasy.—A. D. Rockwell maintains that beginners in Röntgen ray work should thoroughly appreciate that susceptibility to Röntgen ray effects vary as widely as do other physical influences. Idiosyncrasies exist here just as they do to the action of the sun's rays and to various external and internal methods of treatment. Unpleasant and unsatisfactory results are too often ignored in many elaborate clinical reports; failures as well as successes should be frankly recorded. In this way only, can medical and surgical procedure be perfected. The condition and position of the tube, and the time of exposure are the essential features in Röntgen ray treatment, yet with every ordinary precaution occasional cases are met with which defy them and a following dermatitis breaks forth. A marked instance is recorded by the writer. Every patient should be questioned as to any special idiosyncrasy to sunburn, ivy poisoning and external applications. In every case, unless there is important reason for haste, there should be an interval of rest after the first 2 sittings. He suggests that these 2 sittings be 3 days apart, with an interval of 10 days before the third and a week additional before the fourth and then 4 days before the fifth. In all cases of superficial nonmalignant skin diseases, especially in acne, eczema, favus, sycosis, hypertrichosis, etc., extreme caution should be taken at the beginning. Treatment of malignant disease is quite another matter. Here it is often necessary that no time shall be lost, and haste then becomes imperative. [A.B.C.]

4.—Liquefied Air.—A. C. White says: In liquid air we have the nearest approach to absolute zero ever obtained, excepting liquid hydrogen, which is many degrees colder, and is liquefied by the assistance of liquid air. If there is therapeutic value in cold, we have it in liquefied air 312° below zero, and from this we can obtain any desired temperature above that point. If there is therapeutic advantage in having dry cold, we have it in liquid air, for in anything colder than 32° below zero no moisture can exist. If it is desired to produce local anesthesia by cold, we have no means of obtaining the result equal to liquid air, for it is dry, rapid, thorough, clean, and under perfect control. It surpasses all other applications previously in use for the removal of all growths of benign or malignant character, because its application is practically painless, its action more rapid than electric methods, and there is no systemic effect whatever following its local use. If there is value in the therapeutic use of oxygen, we have it in its most concentrated form in liquid air, from which it has been demonstrated we obtain liquid oxygen, and oxygen of much higher percentage and purer quality than obtained in any other way. [A.B.C.]

5.—Primary Carcinoma of the Lung: Diagnosis from

the Expectoration.—F. F. C. Demarest reports that a man of 42, well nourished and apparently healthy, complained of hemorrhage from his throat and pain in the right side of the chest. Physical examination pointed to a normal condition, except an area of consolidation corresponding to the upper third of the right lung. Hemorrhage from the throat had occurred daily for the past 9 months to the extent of about a teaspoonful of blood in 24 hours. The sputum had been examined for tubercle bacilli, but none were found. At the suggestion of Demarest, the patient brought a glass jar containing bloody expectoration, and in this way found a lump of tissue the size of a peanut. The tissue was sent to a pathologist, who pronounced it a slough from a typical squamous-celled carcinoma. The patient was submitted to Röntgen ray treatment without much hope of relief. The patient's death took place 4 months after he came under Demarest's observation, though for some time previous to this there was incoordination in the movement of the right arm and leg, which indicated a metastatic involvement of the opposite side of the brain. No necropsy was secured. [A.B.C.]

New York Medical Journal.

1.—Induced Radioactivity.—S. G. Tracy has found normal salt solution to be one of the best fluids for the receptivity of imparted radioactivity. This fact he believes to be of considerable importance in medicine, as we have thus the hope that the internal administration of "radium fluid" will strike at the root of the disease, in tuberculosis, diphtheria, typhoid, and other infectious diseases; in the protozoal diseases, such as malaria, and perhaps scarlet fever. Another diseased condition in which the induced radioactive salt solution is likely to prove of service is fermentative, gastrointestinal indigestion, with its long train of symptoms, due to autointoxication. It is also hoped that the "radium fluid" will have a favorable effect on malignant disease of the stomach and intestine. It may be used as a local application on compresses, in sprays, gargles, inhalations, collyria, etc. In its use in surgical dressings, compresses can be saturated with this solution and applied over large areas, which could not be reached by the radium rays. As a spray, it may be found useful in catarrhal affections of the nose, throat, and lungs, by coating the membranes with a fine film of radioactive matter. This active matter is antiseptic and will remain in the tissues for several hours. The radioactivity of this active matter may be intensified by exposing the patient to the ultraviolet rays, and by the internal use of quinin. The author is not yet prepared to make a full report of cases under treatment, but announces marked improvement in many instances. [C.A.O.]

2.—Scurvy.—An unusual case of scurvy is reported by Joseph Davidson, in a boy of 17. He had been treated in a hospital for nephritis and mitral stenosis, and had been discharged improved. Later he was readmitted to the hospital as a doubtful case of pulmonary tuberculosis, and was again discharged improved. When seen some time later by the author, he presented a typical picture of scurvy. Hemorrhages into the skin and deeper tissues, ulcerated gums, nose-bleeds, bleeding from the lungs, swelling of the joints, emaciation, pallor, fever, pain, and prostration. He was put on antiscorbutic treatment, and at once began to improve. After 3 weeks he could sit up out of bed; after 6 weeks he could leave the house. His pulse was still small and accelerated and slightly irregular, but the temperature was normal. His heart was slightly enlarged, a systolic murmur was to be heard, the eruption had disappeared for the greater part, the ulcerations were cicatrized, the joints

were much smaller, the gums were healed. Some moist rales could be heard over both apices. His urine contained albumin and casts. He had a paralysis of ulnar and median nerves on both sides, right side worse than left; the thenar and hypothenar muscles, interossei, lumbricales, and the flexors on the front of the forearm were paralyzed and atrophic, there were disturbances of sensation, and partial reaction of degeneration. Since that time the author reports that his condition has not changed very much. Whether the multiple neuritis was caused by hemorrhages into the nerve-sheaths or was of toxic origin, the author is not able to state. He believes that the patient was suffering from a severe attack of scurvy from the very beginning, and that his hemoptyses, which created the suspicion of tuberculosis, his nephritis, endocarditis, and nerve lesion were all of scorbutic nature, and that the absence of the pathognomonic symptoms in the beginning prevented the recognition of the disease. [C.A.O.]

3.—Treatment of the Underfed.—W. S. Ely outlines the treatment for the underfed, or the subese, individuals who may never have been ill, and yet never have been well. They are mostly women, from 18 to 35, who have simply dragged on to adult life in an uneventful way, indefinitely weak, unequal to active exertion; thin; always under weight; comfortable when in repose, but quickly exhausted on slight effort. Good results in these cases are most quickly and surely reached by absolute rest and a diet of milk, chocolate, and raw eggs. The most satisfactory results have been obtained in a hospital, where every detail can receive attention. With the aid of a selected nurse, the treatment which S. Weir Mitchell has outlined in neurasthenic cases is at once instituted. The patient must remain in bed. We may begin with 4 to 8 ounces of milk, or chocolate made with milk, or 2 raw eggs every 2 hours. He prefers to alternate these foods in the order named. During the night the interval may be every 3 hours. In the first 24 hours the endeavor is made to give a quart of milk, a quart of chocolate made with milk, and 6 raw eggs. The amount of food taken is then increased daily. This increase can often be carried with advantage to, or above, 2 quarts of milk, 2 quarts of chocolate made with milk, and 12 or 14 raw eggs a day. To obviate the bilious tendencies of the diet mentioned and to overcome the constipation almost inevitably present, rhubarb and soda tablets may be given after each, or every other, portion of food, from 6 to 20 a day. A moderately coated tongue is expected and does not contraindicate the treatment. Daily baths, massage, passive and active movements of the joints, and the slowly interrupted faradic current, combine to consume the intervals between feedings, to shorten the days, and to impress the patient's mind with the treatment as a whole. So soon as the improvement is considerable, the patient, in summer, sits out of doors, masticates rare beef, and has some cereal added to her diet. [C.A.O.]

Medical News.

January 16, 1904. [Vol. 84, No. 3.]

4. Some Subjective Hints of the Morphin Habit. WILLIAM LEE HOWARD.
5. The Hemorrhagic Diseases and their Allies in the Light of Modern Pathology. F. L. WACHENSHEIM.

2.—Mastoiditis; Sinus Thrombosis; Pyemia, Etc.—Thomas R. Pooley reports that a woman of 25 complained that 2 weeks before appearing at the clinic she was taken ill with grip, and 3 days later developed earache on the left side; the following night there was rupture of the membrana tympani and free discharge. From the discharge, swelling, redness and tenderness, mastoiditis was diagnosed, and an operation deemed urgent. The mastoid cells were opened, and on making an attempt to open the antrum, the sinus was accidentally opened; profuse hemorrhage was stopped by a tampon, and the scraping out of the cells and diseased tissue completed. The patient

apparently did well for 2 or 3 days, and then the symptoms of pyemia became apparent, and arthritis developing in 1 finger, 1 ankle becoming swollen, choked disc appeared, and there were chills and fever. Ten days after the original operation a second operation was performed in which the entire lateral sinus was exposed and emptied of a purulent clot, which extended into the internal jugular; ligation of this vein could not be accomplished owing to the serious condition of the patient, but it was emptied in so far that blood could be forced back into the skull. The wound was dressed in the usual way, the patient remained in a precarious condition, abscess developed at several points, there was pneumonic consolidation of the right lung, and altogether the patient's condition seemed almost hopeless. Finally, however, she recovered sufficiently to be discharged from the hospital after 3 months of confinement, and at the time of writing is steadily gaining in strength. [A.B.C.]

3.—The Surgical Treatment of Acquired Incontinence in Women.—C. G. Cumston reviews the causes of acquired incontinence, classifies its forms anatomically and their proper treatment. If incontinence of urine is present with a congenital displacement of the uterus in antifixion, traction is exercised upward and backward on the urethral orifice by the cervix, and this can be corrected by making a transverse incision over the anterior aspect of the cervix and peeling the bladder off of the organ, as is done in vaginal hysterectomy. Then the wound is simply packed with gauze and allowed to granulate. Cumston has used this method with complete success. When there is destruction of the sphincter with persistence of the urethral canal, the operation may be simply a colporrhaphy, alone or combined with an elevation of the meatus. It is better not to open the urethra, because a fistula may result. When incontinence of urine appears to be due to a more or less complete destruction of the urethral canal, the rational indication is to repair the urethra and replace the organs in their normal relations as far as possible. When bits of mucosa or strips of tissue susceptible of being utilized are still present, they should be used in reforming the canal, otherwise an autoplasmic procedure must be employed. If the loss of substance is far forward, the labia minora may be utilized; but if the injury is farther back, flaps may be made from the vesicovaginal septum or simply from the vagina. If the entire urethra is destroyed, flaps must be obtained from both the vulva and vagina. [W.K.]

4.—Subjective Hints of the Morphin Habit.—W. L. Howard advises in obscure cases surprising the patient by house visits at unexpected hours of the day in order to note the psychic condition at different times, when under and emerging from the influence of the drug. If all accounts agree that the morale of the patient is constantly changing, that where she was formerly truthful she is now careless of her statements, that she makes promises and engagements that are not kept, that her sense of duty has become dull, and her ego exaggerated we can come to the conclusion we are dealing with a user of morphin. [H.M.]

5.—The Pathology and Classification of the Hemorrhagic Diseases.—F. L. Wachensheim holds that with a more thorough understanding of the pathology of the conditions classified under the loose term of hemorrhagic diseases, we should no longer use such classification, but employ a nomenclature in accordance with the pathology of the several conditions under the group before named. He discusses the auto-genetic hemorrhagic diseases, the scorbutic diseases, the exogenic hemorrhagic diseases, the chemic blood poisoning, and the infectious hemorrhagic diseases. He says: Summing up, we find that hemophilia, congenital or acquired, is a toxemia with secondary autoimmunization to a quasinnormal function; that the scorbutic affections are chemic autointoxications, hemorrhagic only because the blood is especially involved; and that the purpura rheumatica group is only a manifestation of ordinary rheumatism or sepsis. After this exposition of their very diverse nature, it seems clear that the old class of the hemorrhagic diseases has become obsolete, should be relegated to the domain of historic medicine, and cease to appear in our monographs and textbooks to further puzzle the student and physician. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The Myelogenous Origin of Acute Lymphocytic Leukemia.—The nature and interrelations of the different varieties of leukemia are subjects of perennial interest, and while we have learned much during recent years, discussion is still rife and much remains to be learned. The conviction, however, is gaining ground that although the clinical manifestations and the blood pictures justify the almost universally employed division of the disease into two clinical varieties, generally called the lymphatic and the myelogenous (or splenomedullary), the sharp anatomic distinction between these varieties insisted upon by Ehrlich and his school is not tenable. To this phase of the subject, A. O. J. Kelly has contributed a paper¹ based upon the clinical and anatomic study of 4 cases of acute lymphocytic leukemia. The evidence that has tended to throw doubt upon the absolute nonidentity of the two clinical varieties of the disease may be summarized as follows: 1. The occurrence of cases of so-called acute lymphatic leukemia with little or no enlargement of the lymph-glands—of which a considerable number have now been reported by Pappenheim, Walz, Michaelis and Wolff, Dorothy Reed, Hirschclaff, Körnőczy, Spencer, Hayem and Bensaude, Kelly, and others. 2. The demonstration, particularly by the writers just mentioned, of the predominance of lymphadenoid changes in the bone marrow in every case of lymphatic leukemia in which the bone marrow has been examined—a demonstration, however, that merely emphasizes the original observations of Neumann made many years ago. 3. The fact that the distinctions between the lymphocytes and the granulocytes are of degree rather than of nature, since the lymphocytes are unquestionably ameboid, some of them possess granules in their protoplasm, and there is some evidence of the occurrence of an active lymphocytosis. 4. The fact that the lymphocytes and the granulocytes (myelocytes and the granular cells of the circulating blood) develop from a common ancestor in the bone marrow—at least in pathologic states. 5. The fact that even clinically there is no sharp dividing line between the two forms of the disease. Kelly points out that rather than two forms of the disease there are extremes of type, that atypical and transitional (intermediate or mixed) forms do occur, and that while we have hitherto thought that acute leukemia is always lymphocytic, and chronic leukemia either lymphocytic (the rarer form) or myelocytic (the common form), apparently trustworthy evidence has recently accumulated that tends to show that acute leukemia may be, though rarely, myelocytic, and contrary to the rule, certain of the chronic lymphocytic cases reveal an unusually large number of large lymphocytes, and some of the apparently acute cases may be of the small lymphocyte type.

The bone-marrow changes in acute lymphocytic leukemia are of extreme interest and importance, not only in themselves, but also because of their bearing upon certain moot points in the development of leukocytes. That which is of especial importance is that the bone marrow appears to be always involved in lymphocytic leukemia; furthermore, Kelly states that there is good evidence for believing that whether or not the lymph-glands are enlarged, the typical leukemic blood picture does not develop until the bone marrow becomes affected; that since, therefore, the bone marrow changes appear to be the lesions, both varieties of leukemia are myelogenous in origin, and he prefers the terms lymphocytic and myelocytic as suggesting the distinguishing features of the bone-marrow proliferation and the blood

changes in the two classes of cases. As regards the development of lymphocytes and granulocytes from a common ancestor in the bone marrow, it is stated that tentatively much importance is attached to the large mononuclear nongranular cell of the bone marrow which is thought to be capable, under the influence of divers stimuli, of assuming basophilia of its protoplasm and becoming a lymphocyte (the cell so numerous in the blood in lymphocytic leukemia), or of assuming neutrophilic granules and becoming a myelocyte (in the ordinary sense). Probably the development in one or the other of these directions is influenced by the nature of the chemotactic agent concerned, since it is believed that both types of leukemia are the result of chemotactic influences. The entire subject is of much interest, and while the myelogenous origin of acute lymphocytic leukemia seems to be open to little doubt, many points await solution—not the least important of which is the determination of the sequence of events in the development of the leukocytes, more especially the development of lymphocytes and of granulocytes from a common ancestor.

REVIEW OF LITERATURE

Palpation and Auscultation of the Normal Large Pylorus.—A palpable, normal large pylorus has frequently been mistaken for a tumor. There are certain definite points of difference, however. P. Cohnheim¹ briefly reviews the subject, showing that the palpable pylorus changes its consistency, and alternately vanishes and disappears. The pylorus can be differentiated from the transverse colon by the direction of peristaltic movements. These can sometimes be seen, but are more frequently felt; in the stomach they are always from left to right, while in the colon the movements are from right to left. The phenomenon is exclusively observed in persons with lean, relaxed abdominal walls. Very often there is enteroptosis, with diastasis and relaxation of the recti muscles. It frequently occurs after rapid emaciation, hence is especially common in patients with pulmonary tuberculosis. The author reports 16 cases observed by himself. A permanent hardness of the pylorus points to malignant disease. [B.K.]

Study of the Colon and Rectum.—In a clinical lecture on this subject, C. G. Stockton² speaks of its great importance, and suggests that the comparative leisure of the early years of practice should be partly employed in a study of this much neglected field. The ordinary practitioner has surprisingly little knowledge of the feces. While precise investigation of this material is a complex question, a great deal of important information may be gained by means of the unaided eye and experience. Among the points to be thus investigated are the weight of the feces as compared with the amount of food ingested, the completeness of the disintegration of the food substances found in the stools, and the consistency of the fecal matter. Attention is next directed to the importance of examination of the rectum, which should be made in all cases of intestinal disturbance. Precisely the right instruments should be employed for this work. Among them are a small tubular speculum, 1 inch in diameter, with a conical end and a fenestrum on one side. Another useful instrument is Martin's proctoscope and another of considerable value is the Wales sound. The treatment by inexperienced hands of some of the more important lesions of the rectum and colon is not recommended by Stockton, but he insists that every physician should be able to make the diagnosis. [A.G.E.]

Diabetes Insipidus in a Case of Diffuse Ependymitis of the Floor of the Fourth Ventricle.—This case, which is fully covered by the title, is reported by K. Pichler.³ [D.R.]

Involvement of the Red Bone Marrow in Acute Infections.—The investigations of E. Fraenkel⁴ show that in the vast majority of infectious diseases, organisms are found in the red bone marrow. These organisms are either those of the

specific disease, or those of a mixed or secondary infection. In cases of typhoid fever the author invariably found the typhoid bacillus in the marrow, in all stages of the disease. In chronic pulmonary tuberculosis, on the other hand, the organisms were very rarely found. The presence of the specific organism in the bone marrow is also very rare in diphtheria, but other organisms, especially the streptococci, are frequently found in this disease. In scarlet fever streptococci are almost invariably found. The period of the disease, at which the organisms reach the bone marrow, varies for each infection, as does also the length of time during which the organisms may be found there. In typhoid fever they may be found in the marrow even after the local lesions in the intestines have healed. In erysipelas also the organisms are found in large numbers after all local symptoms have subsided. These organisms may cause injury to the bone marrow in many ways, considerable pathologic change being found after death. The result during life is an alteration in the composition of the blood, since the bone marrow plays so important a part in blood formation. [B.K.]

The Part Played by Light in the Cure of Tuberculosis.—Baradat¹ says light enriches and nourishes the blood, produces a great reserve of energy, it stimulates the nerve ends and vivifies the nerves; it acts upon the skin, accelerates its action, and is able to renew the tissue. He says the light ameliorates and renews the tuberculous soil, it attacks the bacillus directly. He reports 2 cases that had been treated for 6 weeks; after 6 days' treatment the night sweats ceased, the cough diminished, in spite of the unfavorable weather and defective care, and the number of bacilli decreased in the sputum. Baradat says the sun baths can be given on the sea, where the light is reflected by a vast mirror—the waves. He further says there should be no curtains before the windows, since the light after passing through them is not so pure as the direct solar rays. [J.F.]

At What Age do Tabetics Die?—P. Marie and P. Mocquot² have investigated this question. They found that out of 66 tabetics, 51.5% died after 60 years of age, and 83.3% died beyond 50 years. Of 58 patients still living, 43.1% had passed their fifty-fifth year, and 68.9% were beyond 50 years of age. The conclusion is that locomotor ataxia is a disease which has little influence on the duration of life. [B.K.]

The Physiopathologic Effects of Electricity of High Tension and Frequency Upon Normal Cutaneous Surfaces.—Since demonstrations of d'Arsonval and of Tesla, it is known that the vital organism can endure immense discharges of electricity. The application of newer physiochemic ideas in our modern therapy makes it interesting to know by experiments the possibilities and chances we run in using electricity and other modes of ethereal motion. G. Arienzo and S. Fabozzi³ publish tests of the skin of rabbits subjected to electric currents under various conditions. A single application of 20 minutes after 24 hours induces a local hyperemia, which on microscopic examination shows an infiltration of mononuclear and polynuclear leukocytes whose protoplasm is markedly acidophile; this occurs mostly within the subcutaneous connective tissue. If the skin be not examined for 2 days, on the second of which another similar electric application is given, we observe the stratum corneum disintegrated and its place occupied by a granular substance which includes the outer layer of damaged epithelial cells, these undergoing a "pronounced necrobiosis, and with an exudate, as above, invading the connective tissue, and extending upward." Fusion of several cells and confusion of their nuclei develop a more or less advanced stage of pycnosis and of kariorexis. Hyperemia is intense. If the test is made 3 days, a crust forms on the skin, due to the detritus of disintegration. These crusts appear umbilicated, and with the further lengthening of the times of application, the effects are similar but greater. After 5 days the detritus contains a yellowish deposit derived from white cell invasion and disintegration. On the prolongation of recovery, after 10 days, these lesions are obliterated and regeneration

nearly complete. What value will these tests have in indicating a method of scar removal? [T.H.E.]

Diagnosis of Hepatic Abscess after Dysentery.—Schlayer¹ confirms the existence of a hyperleukocytosis in liver abscess, no matter from what cause. He made leukocyte counts in 11 cases; in 10 of these the white blood cells varied between 18,000 and 62,000 in the days before operation. Dysentery abscesses give a higher degree of leukocytosis than abscesses after other conditions. Dysentery alone will give a leukocytosis. [E.L.]

EDITORIAL COMMENT

The Radical Cure of Corns.—The treatment of corns has largely fallen into the hands of irregular practitioners, partly from the false pride of some who have felt that such trivial ailments are beneath their notice, and partly because the possibility of speedily curing them has not been sufficiently appreciated. It is specially unfortunate that such is the case, for several reasons; not only do very many people suffer a great deal of unnecessary discomfort from them, but not unfrequently serious consequences result from paring corns, from the application of corn cures, or from the bad management of quacks, who set up as chiropodists. We have seen a case in which gangrene involved a large part of a foot, the result of infection from paring a corn. In numerous other cases we have seen infection of greater or less gravity result from the treatment of quacks and the application of patent corn cures. We know of one death resulting from infection following treatment by a so-called chiropodist. For the benefit of those willing to treat corns we refer to a recent contribution by E. Harding Freeland, F.R.C.S.² A fact brought out by histologic study which seems of some importance is that a small bursal sac sometimes exists in the subcutaneous tissue between the corn and the underlying bone. The methods of treatment in general use are unsatisfactory, for whether chemic agents or removal by instrument be employed, the separation is usually not deeper than at the junction of the stratum corneum and the stratum lucidum; the part from which the growth is reproduced is left behind and recurrence is inevitable. Removal below the horny layer is impossible by the usual means without giving great pain. Freeland finds that so-called soft corns do not differ in any way from hard corns, except that the surface is macerated by heat and moisture between the toes, where soft corns commonly exist. He has treated cases successfully by complete excision, carried entirely through the layers of the skin, and he calls special attention to the necessity for removing the bursa above mentioned, which if left behind frequently becomes inflamed and painful. When corns exist because of some deformity of the foot, such as bunions, hammer-toe, or some variety of pes cavus, the treatment should be directed to the deformity, and we should not be in a hurry to excise the corn. In other cases he has been successful in relieving patients by complete excision. It seems almost unnecessary to call attention to the necessity for specially careful, antiseptic precautions in any operation on the foot, no matter how trivial. We know from the experience of many generations of our profession, how frequently tetanus follows injury of the feet. It is also, perhaps, superfluous to mention local anesthesia with Schleich's solution (cocain, 1 to 1,000, with morphin in normal salt solution) in this connection. If members of the medical profession can convince the public that they are prepared to permanently relieve them of an affliction which in many cases is a source of constant misery, by a comparatively slight operation, they

will not only add to their incomes what is now going to quacks, but they will also remove a grave danger of infection and increase their reputation. We do not condemn local applications, filing, scraping, pads to relieve pressure, or other palliative measures in the hands of careful, competent men, and in ordinary cases, but we believe palliative treatment will prove unsatisfactory in many large, deep corns, situated where subject to constant pressure. In such cases excision gives complete, permanent relief.

REVIEW OF LITERATURE

Three Successful Laparotomies for Intestinal Perforation in Typhoid Fever.—Richard H. Harte¹ reports a series of 13 operations for intestinal perforation in typhoid fever, with 3 recoveries. The histories of the 3 successful cases are given in some detail. The first was a male patient of 29, perforation occurring in the third week. This was recognized soon after its occurrence, but consent for operation was not gained for 5 hours. Under ether narcosis laparotomy was done and the perforation found and closed. Patient made a complete recovery, although an empyema developed which had to be opened and drained. The second was a male patient of 39, who was admitted to the hospital on about the tenth day with symptoms of peritonitis. Under ether, laparotomy was done, the perforation found and closed. The abdomen was flushed and the patient recovered. The third was a male patient of 13. Perforation occurred on the forty-sixth day of the disease. Ether was given, laparotomy done, gangrenous appendix found and removed, 2 perforations closed, and the patient recovered. The writer asserts, in discussing various symptoms, that abdominal rigidity as understood by the internist and the surgeon, are different things. It is the keynote to early detection of perforation in the large proportion of cases. Success depends, of course, on the early recognition of perforation and prompt operation, even in the presence of profound shock. Every hour delay proportionately decreases the chance of recovery. He prefers incision along the border of the right rectus, thoroughly flushing out the abdominal cavity with salt solution, and then with equal parts of salt solution and hydrogen peroxid, and finally douching with salt solution. He has collected 332 cases in literature. In 96 the median incision was made, with a mortality of 78%. In 123, has the right lateral incision shown a mortality of 68%. Mortality among males was 78%. Among females 61%. According to his tables, the mortality has steadily diminished. From 1884 to 1888 it was 90%; from 1889 to 1893, 87%; from 1894 to 1898, 74%; from 1899 to 1903, 69%. [A.B.C.]

Present Status of Stomach Surgery.—A. J. Ochsner² says that most diseases of the stomach which cannot be relieved by internal medicine must ultimately be treated surgically. In the majority of these cases there is faulty drainage, whatever be its cause. Of all the operations upon the stomach, gastroenterostomy is most commonly indicated, but it is yet too early to make a definite statement regarding the best method of performing it. In cases of excision of the pylorus the Murphy button secures ideal conditions. When the pylorus is not excised the opening made by the button is likely to contract and other methods are to be preferred. Ochsner has performed gastroenterostomy in 71 cases, 4 with needle and thread, 34 with the Murphy button, and 33 with the McGraw ligature. The latter method has given very satisfactory results but experience is too limited to justify definite statements regarding its real value. Ochsner gives minute directions for the employment of this device. Of the methods of performing pyloroplasty, that of Finney is undoubtedly the best but the operation has not been satisfactory in Ochsner's experience. The results of pyloroplasty will become more and more favorable as patients come to the surgeon before the malignant disease has become so far advanced as is usual at present. [A.G.E.]

Colotomy and Colectomy.—F. T. Paul,³ surgeon to the Liverpool Royal Infirmary, states that modern colotomy, for malignant disease, has gained in favor. This is due to a lowered mortality and an improved artificial anus, the latter being

the most potent factor. Following the recent improved operations usually a very fair control is established in most cases, and prolapse rarely occurs. Cripps' is a method which has met with much favor, but the writer prefers Allingham's in many instances. The results desired from colotomy are relief, safety, and comfort. He uses the glass-tube method, believing that this does not increase the risk to life and it permits the bowel to be opened at once, the patient relieved of the distressing condition, and the operation to be completed at one sitting. As regards comfort, the essentials are a high operation, a small wound, opening the highest portion of the colon available, the formation of a good spur, the use of a good plug, and the cultivation of a regular habit of the bowels. Even when colotomy only is intended before operation, sometimes colectomy is found to be necessary, or the reverse may be the case. It is the great misfortune that malignant disease of the bowel is usually discovered too late for colectomy to be practicable; generally malignant disease has progressed so far before symptoms appear that colotomy is the only operation which we can consider. [A.B.C.]

Adrenalin in Urinary Retention of Prostatic Enlargement.—E. F. Rodríguez¹ compares reports of its successful employment, notably, cases by Chassaignac, of New Orleans, who advises the preliminary injection of a suitable solution of adrenalin preparation, when sounds are to be passed, in order to minimize the chance of hemorrhage, which in prostatic cases often is severe and obstinate. Rodríguez gives technic, as in a case of his own, a patient, 75, male. Symptoms due to the prostatic lesion were progressively and easily diminished. Among other instruments, a Guyon sound and a Frank syringe are needed. Adrenalin 1.0 gm. of 1-1,000 solution, used with a Keyes-Ultzman syringe 5 minutes before the operative proceeding. [T.H.E.]

Hemorrhage into the Bursa of the Patella.—J. B. Christopherson² reports that a soldier fell from a horizontal bar striking his knee; no external scar or trace of bruise followed, but the knee became swollen and semiflexed, presenting the evidence later of a chronic synovitis without effusion; there was no fluctuation, but there were present 2 irregular thick transverse ridges across the patella simulating coils thrown out after fracture; they extended beyond the limits of the patella. It was thought to be a case of tuberculous disease of the knee-joint. No improvement followed immobilization, strapping, etc., and a 15 cm. (6 in.) vertical incision over the patella showed the bursa over the periosteum thickened to the extent of a quarter of an inch, which, on being opened, was found filled with an old extravasation of blood which had become partially organized. The bursa was dissected out, a small amount of fluid aspirated from the joint was found normal, the wound closed, a splint applied, and the soldier made an uneventful recovery. The author is of opinion that this accident is of sufficient frequency to warrant its being mentioned in the textbooks on surgery, to prevent a mistaken diagnosis of tuberculous disease of the joint or fracture of the patella. [A.B.C.]

Surgery of the Biliary Passages.—Maurice Richardson³ says that in some instances when symptoms point to gallstones none are found and in other instances symptoms pointing to other lesions are found to be due to the presence of gallstones. The practical point is that one seldom errs in exploring the right upper quadrant in these cases as some defect or active lesion will be found. In connection with the lesions of gallstones there are many questions of operation and technic yet to be settled. Richardson makes systematic exploration of the structures in the right upper quadrant of patients whose abdomens have been opened for other purposes, as a rule during aseptic pelvic operations. Incisions are not prolonged for this purpose and sepsis and shock are, of course, contraindications. The results of these examinations have been of value. In several cases gallstones have been found although the patient had never been conscious of a single unpleasant symptom. Questions concerning the connection between gallstones and digestive disturbances and the relation between gallstones and

enlargements of the pancreas are likely to be settled by these systematic explorations. As to the time for operation upon gallstone cases, Richardson compares the results of early and late operations, saying that the chapter of disaster and death in lesions of the biliary passages is a sequel to the chapter dealing with the prolonged effects of those lesions. His own success has been proportionate to the promptness of surgical intervention after the establishment of the diagnosis. [A.G.E.]

TREATMENT

SOLOMON SOLIS COHEN

E. LINDAUER

L. F. APPLEMAN

REVIEW OF LITERATURE

Treatment of Eczema of the Free Borders of the Eyelids.¹—The general treatment must consist in regulation of the diet and in aiding the elimination of effete materials. The diet should consist of nutritious and easily digested food, the avoidance of alcoholic beverages, fat meats, pork, cheese, salt fish and highly seasoned foods. A mild laxative should be administered every evening before retiring. Local treatment consists in cleansing the parts night and morning with a hot boric acid solution. This should be followed by the application of zinc oxid ointment to the margin of the lids. After the acute inflammation has subsided, the following ointment may be applied:

Yellow oxid of mercury . 0.5 gm. to 1 gm. (7 gr. to 15 gr.)
Pure vaselin 20 gm. (5 dr.)

The following preparations may also be used:

Lead acetate 0.25 gm. (4 gr.)
Benzoinated lard 25 gm. (6 dr.)

Or,

White precipitate 0.1 gm. (1½ gr.)
Oil of birch 0.1 cc. (1½ m.)
White vaselin 8 gm. (2 dr.)

These may be applied upon retiring. [L.F.A.]

Mineral Waters in Chronic Hyperemia of the Liver.

—Chronic hyperemia of the liver as a symptom of stasis in the portal circulation resulting from overfeeding, from a sedentary mode of life, or from habitual constipation, as well as the form induced by disease of the heart, the lungs, the spleen, or the uterus, is frequently subjected to mineral-spring treatment. Kisch (Physiologic Therapeutics, Vol. ix) advises that when the condition occurs in vigorous persons with good powers of resistance, and the liver is found to be large, hypostatic, and tender on pressure, drinking-cures at Carlsbad, Marienbad, Kissingen or Homburg be undertaken; for flabby, anemic, scrofulous individuals, drinking-cures at Franzensbad, Elster, Soden, Ems, and Gleichenberg are suitable. Hinsdale notes that among American waters suitable for the first group of cases are: Bedford Springs, in Pennsylvania; Ballston Spa and Saratoga Springs, in New York; Greenbrier White Sulphur Springs, in West Virginia; Crab Orchard Springs (Epsom Spring), in Kentucky; American Carlsbad Springs, in Illinois; Byron Springs, Gordon Springs, and Coronado Springs, in California; Cañon City Mineral Springs and Springdale Seltzer Springs, in Colorado. For anemic and scrofulous individuals the waters of Sharon Springs (Chalybeate Spring), in New York; Cresson Springs (Iron Spring), in Pennsylvania; Sweet Chalybeate Springs and Healing Springs, in Virginia; Geyser Spa and Harbin Hot Springs, in California; Manitou Springs and Royal Gorge Hot Springs, in Colorado; and Castle Creek Hot Springs in Arizona, may be employed. The springs of the first-named group—sodium sulfate and sodium chlorid waters—are indicated also in cases of fatty liver as a symptom of general obesity. In the presence of marked general obesity, and in combination with arthritis, Marienbad or, in the United States, the Hot Springs of Virginia, Las Vegas Hot Springs in New Mexico, or the Hot Springs of South Dakota are appropriate. When there is a tendency to diarrhea, the alkaline thermal waters of Carlsbad and Ems may be used with advantage. For scrofulous individuals, Homburg, Kissingen, and Wiesbaden are of benefit. In the presence of marked anemia, Franzensbad and Elster are to be preferred.

Urotropin in the Prophylaxis of Scarlatinal Nephritis.

—The disinfectant action of urotropin (ammonium-formaldehyd) as evidenced by its effects in vesical catarrh, pyelitis and phosphaturia, induced Widowitz¹ to employ it in scarlatina with a view of preventing nephritis, which is probably caused by the as yet undetermined scarlatinal microbe or its toxins; and an antibacterial agent applied to the site of the infection might prevent the pathologic changes which mark the renal affection. He administered from 5 cg. to 48 cg. (½ gr. to 7½ gr.) 3 times a day for 3 days at the onset of the disease and at the beginning of the third week when nephritis most commonly occurs. His 102 patients were children from 1 to 15, and an adult of 21. The remedy was always well borne. In none of them did nephritis occur, though Johannessen has seen it in as many as 90% of scarlatinal cases. Its absence in this series of unselected cases may possibly be an accident, but further clinical trials are worth while. [It has long been my practice to use this drug in typhoid fever to keep the urine disinfected and I have also used it in scarlatina, erysipelas, and other infections commonly attended with kidney complications: usually with beneficent results. s.s.c.]

Balneotherapy in Cardiac Disease.—The employment of baths in the treatment of cardiac disease must be governed by a thorough knowledge as to whether the patient is suffering from heart disease with hypertrophy and increased arterial tension, or with valvular disease of rheumatic origin.² In the first class of cases, sedative baths must be used which do not raise arterial tension; in the second class, stimulant baths which act as tonics to the heart must be used. Kisch directs that hot baths shall be used when it is necessary to obtain vasodilation, a decrease in arterial tension and increase in the pulse-rate. Cold baths produce opposite results. Carbonic acid in the bath acts as a distinct stimulant to arterial tension. Vapor baths have a very energetic effect upon the circulation. At first the pulse-rate is increased and the arterial tension raised; it is only after 10 or 15 minutes that the arterial tension falls; for this reason Kisch limits these baths to cases of obesity without myocardial or valvular lesions. [L.F.A.]

PATHOLOGY.

J. EDWIN SWEET

EDITORIAL COMMENT

Human and Bovine Tubercle Bacilli.—An important contribution to our knowledge of the biologic differences between the human and the bovine tubercle bacillus was made by Dr. Theobald Smith at the recent meeting in Philadelphia of the Society of American Bacteriologists. Dr. Smith has studied the effect of the growth of the bacilli upon the reaction of an acid glycerin-bouillon medium. Starting with a medium the acidity of which is equivalent to a 2% solution of phenolphthalein, it is found that both groups of bacilli cause a gradual neutralization of the acid until about the end of the first month's growth; at this time the acidity may have fallen to around 1% of phenolphthalein. From this time on, however, a marked change occurs; the bovine bacillus causes further neutralization of the acidity of the medium until a point is reached when the medium is but slightly acid, or even slightly alkaline, and remains during further growth at this point. The human bacillus, on the other hand, after having caused a gradual neutralization during the first month, begins to produce an increasing acidity of the bouillon, until after two to three months the acidity again equals or slightly exceeds the original acidity of about 2%. Sometimes the human bacillus does not cause a return to the normal acidity, but follows an irregular curve, the acidity of the medium rising and falling slightly around a point equal to about 1% of phenolphthalein. This method will not serve as a means of differential diag-

¹ Journal des Praticiens, Vol. xvii, No. 32, 1903, p. 504.

¹ Wiener klinische Wochenschrift, October 1, 1903.

² Journal des Praticiens, Vol. xvii, No. 32 1903, p. 507.

nosis because of the length of time required to construct such curves. The discovery is of no little interest, however, since it proves that the two groups of bacilli show a distinct difference in one at least of their biochemic characteristics, in addition to the wellknown differences in their biologic characteristics. It still remains a question for discussion whether the one group can be forced by artificial conditions to assume the biologic and biochemic characteristics of the other group.

The Occurrence of Diphtheria-like Organisms in Cow's Milk.—D. H. Bergey reported before the same society some interesting conditions which he has found during a regular examination of cow's milk direct from the udder. He had isolated in a number of instances, in several in pure culture, organisms which belong to the group of bacilli called by the meaningless term "pseudodiphtheria" bacilli—that is, bacilli which share to a greater or less extent the characteristics of the true diphtheria bacillus, the main difference being that they are not pathogenic, while the true organism is. If we consider bacteriology from the standpoint of evolution, there can be no doubt that these minute plant forms, now pathogenic, were once pure saprophytes; there is also no reason to suppose that the conditions which determine the parasitic or saprophytic existence of a microorganism do not still exist, and that many true sporadic cases of diphtheria are not to be explained by a coincidence of the conditions which make parasites out of such organisms as Dr. Bergey has encountered. The proof of these interesting problems will come with a more complete knowledge of the life history of bacteria.

The Artificial Cultivation of Trypanosomes.¹—The work described by Dr. F. S. Novy before the same society marks an advance in our knowledge of the disease producing parasites. Novy has succeeded in cultivating the flagellated protozoon known as the trypanosome, found quite generally in the blood of rats, in the water of condensation of an agar tube to which rabbits' blood had been added. The agar is necessary in this combination, acting possibly by absorbing the products of metabolism, which would eventually inhibit the growth of the organism. Two species, the trypanosome found in the common rat, and the Nagana parasite, have thus been carried through many generations; the later generations retain their full virulence. Organisms of this group have been identified as the cause of a number of diseases of animals, especially of horses, and in a few diseases of man, the best known of which is the so-called sleeping sickness of Africa. At a recent meeting of the Pathological Society of Philadelphia, Dr. W. M. L. Coplin demonstrated the trypanosome of Lewis, which he had found in the blood of rats caught at the Municipal Almshouse. Dr. Coplin described an important aid in finding the organisms; if suspected blood be placed in the centrifuge, the trypanosomes having a lower specific gravity than the red cells and a higher specific gravity than the white cells, will collect in a white ring between the erythrocytes and the superimposed ring of white cells. Dr. Novy thinks that careful observations may show the presence in our own country of the trypanosomes in the blood of man, particularly in the Southern States.

The Report of the French Yellow Fever Commission.—During the past 14 months a commission, composed of MM. Marchoux, Salimbeni, and Simond, has been at work in Rio de Janeiro upon yellow fever, under a subsidy of the French Colonial Ministry. The exhaustive report recently published² is of interest to American physicians, because it forms a magnificent testimonial to the thoroughness and accuracy of the American workers

in Havana. The results obtained by Reed, Carroll, Lazear, and Agramonte have been substantiated in every detail by the French scientists, and it must also be added that the work in Brazil has brought forward nothing new. The virus of yellow fever is found in the blood of the patient during the first three days; on the fourth day it has disappeared. The disease is transmitted by a mosquito, the *Stegomyia fasciata*; an incubation period of 12 days must intervene between the time of the infection of the mosquito and the time when it can cause the disease by infecting a human being. The organism of the disease passes through a Chamberland F filter—but not through a Chamberland B—a filter with finer pores; it is probably to be classed in the group of the so-called "invisible" microbes. The serum of convalescents contains preventive properties, which confer an immunity appreciable after 26 days; this serum can apparently be used as a therapeutic agent. The infectious agent could not be determined, but it is not a yeast, as has been claimed—a point also recently proved by Carroll (paper read before the meeting of the Society of American Bacteriologists). The report is very complete and reflects great credit upon the members of the French Commission; at the same time it reflects still greater credit upon the American workers in Havana—that they left nothing to be rectified and nothing to be discovered, except the organism which causes the disease, and this discovery doubtless awaits an advance in our technical methods.

REVIEW OF LITERATURE

The Histogenesis of Elastic Fibers at the Organization of an Aleuronat Exudate.—J. Schiffmann¹ concludes from his studies upon rabbits that elastic fibers develop synchronously with the young connective tissue fibrils, in an arrangement analogous to these, and that they develop before the newly-formed vessels are provided with elastic fibers; they are formed as continuous fibers, and are not derived from portions of the protoplasm; there is no impregnation of connective tissue fibrils with elastic granules.

Primary Carcinoma of the Extremities.—M. von Brunn² gives a collection of cases from the literature since the work of Volkmann, in 1890, and of 46 cases from his own clinic, 20 of which have never been described. The literature contains 99 cases since 1890, which together with those collected by Volkmann, make a total of 368 observations of primary carcinomas of the extremities. Of these, 227 arose on the basis of chronic inflammatory processes, 46 from warts and naevi, 16 from congenital warts, and 48 on apparently normal skin. The fingers and the backs of the hands are the parts of the upper extremity most often affected; the carcinomas of the lower limb are limited to the leg. Over two-thirds of the cases occurred in males. These carcinomas are the strongest proof of the fact that chronic inflammatory conditions favor the development of these tumors.

A Case of True Accessory Lung.—R. Lewisohn³ discusses the 12 recorded cases of this rare anomaly, and describes his own case. The accessory lung resembled in appearance the spleen, was attached to the basal surface of the lower lobe of the left lung, and received a large branch from the aorta. The accessory organ was completely atelectatic; microscopic examination revealed abnormal development of large blood-vessels; the alveoli are lined with cylindric epithelium, and contain a great number of desquamated cells; bronchi lined with ciliated epithelium were found. A discussion of the embryology of these malformations closes the article.

The Change and Transportation of Fats in the Cornea.—J. Arnold⁴ concludes that a part at least of the fat-forming material or the fat itself, which appears in the cornea during disease conditions, for example, in inflammatory processes, has been brought to the cornea, and may, therefore, be considered

⁴ C. f. allg. Path., etc., 14, 19.

of exogenous origin. Soaps may be changed into fats by the granules of the cells found in the cornea.

Advance in Pathology in Relation to Dermatology.—E. Kromayer¹ gives the seventh yearly review of the literature bearing upon the phases of pathology in relation to dermatology. The number of publications is less than in former years. Kromayer calls especial attention to the discovery of the "syphilis bacillus" by Joseph and Piorkowski (the cultivation of a bacillus, probably *Bacillus xerosis*, upon placentas, the organisms being found in syphilitic sperma,² the inoculation of syphilis into swine by Neisser,³ the work of Matzenauer on noma,⁴ the publication of Matsura⁵ on the variations of the thickness of the hairs during health and disease, and to the paper of Kromayer⁶ on "New Biologic Relations between Epithelium and Connective Tissue, Desmoplasia." In this article Kromayer advances the idea that in the normal organism epidermal cells become dislocated into the connective tissue, and change by metaplasia into connective tissue cells. Kromayer claims that the soft naevi are due to such a change in the biologic characteristics of normal cells.

Sublamin as a Fixing Solution.—V. Klingmueller and F. Veiel⁷ claimed for the new salt of mercury, ethyldiaminsulfate of mercury, that it presents the following advantages over corrosive sublimate as a fixing agent; no precipitates are formed, the tissue is easily stained, and the natural color and nature of the organs are hardly changed.

Degeneration of Elastic Tissue Analogous to Fatty Metamorphosis.—L. Jores⁸ has encountered fatty metamorphosis of the elastic fibers of the intima of the aorta in arterial sclerosis, and in one instance in the elastic fibers of the trabeculas of the spleen. The granules in the fibers give the Sudan reaction, and also stain black with osmic acid. This discovery is of importance, since the condition of fatty metamorphosis has always been associated with the protoplasm of tissue cells and the elastic fibers are considered as belonging to the connective tissue. Jores does not consider the possibility of a pure fatty infiltration, a passive process, but thinks the elastic fibers are primarily affected.

The Presence of Chorioepitheliomas and of Cauliflower Growths in Teratomas.—F. Schlagenhauer⁹ describes a teratoma with the characteristic tissue of a chorioepithelioma, which was found in the testicle, and which caused metastases. He inclines to the theory that the chorioepithelial tumors arise from impregnated polar bodies, and since of fetal origin, such tumors can be found without any relation to previous pregnancy, and even in the male, as in this case. He further examined various teratomas, and concludes that tumor formations of the cauliflower type can be found in teratoid tumors of the testicle.

Studies on Sheeppox.—A. Borell¹⁰ reports the results of attempts to prevent the ravages of sheeppox, arising from endemic foci in France itself, and imported yearly into France with Algerian sheep. The methods perfected in the laboratory have been applied *en gros*, and thousands of sheep were treated. The disease must be combated both by an antiserum, since endemic foci of the disease exist, and infected animals must be treated, and by an active immunization to prevent infection from these endemic foci and from the Algerian sheep. The active immunity is conferred by inoculating with a virus which has been attenuated by age; the antiserum is obtained from animals treated with successive doses of the virus. The organism of the disease is not known—doubtless one of the "invisible" microbes. The results reported by Borell will result in the possibility of saving thousands of sheep yearly. [J.E.S.]

Beer Yeast and Suppuration.—E. Sergent¹¹ finds that the staphylococcus, when rubbed gently into the skin of the rabbit produces a great number of small pustules appearing on the

second day, which become surrounded with an aureole on the third day, begin to dry on the fourth, and heal with desquamation on the fifth and sixth days. If the rabbits are given per os large quantities of yeast, 20 gr. to 30 gr. per day, or 50 cc. to 80 cc. of a watery extract of yeast filtered through a porcelain filter, the development of these pustules is hindered. If given before the inoculation of the staphylococcus, the pustules are very limited. The same effect is obtained by using yeast in cases of furuncle in man, although there are persons who do not respond to such treatment. [J.E.S.]

Inoculation of Syphilis into the Ape (Bonnetchinois).—C. Nicolle¹ inoculated syphilitic material into 3 apes. After 15 to 19 days' incubation, papulosquamous eruptions appeared, in 1 instance a focus of subcutaneous induration accompanied by hypertrophy of the corresponding glands, healing after 10 to 23 days following the appearance of the symptoms. [J.E.S.]

Report on Bovine Tuberculosis.—V. A. Moore² has issued a reprint which contains beside a general discussion of bovine tuberculosis the conclusion that "the bacteria of human and bovine tuberculosis belong to the same species, but as they are found in the lesions of man and cattle they are differentiated from each other by distinct varietal differences. The bacterium of human tuberculosis is rarely the cause of death in cattle. There is much evidence that the disease is transmitted from cattle to the human species less frequently than was formerly supposed." [J.E.S.]

The Presence of Lymph-glands in the Substance of the Cheek and their Clinical Importance.—Trendel³ finds with relative frequency lymph-glands situated in the subcutaneous tissue of the cheek in front of the masseter and rarely below the buccinator, either on the buccinator, on the outer side of the lower jaw or of the upper jaw. These glands receive ducts from the nose, upper lip, regions of the eye, cheek, and temple, the mucous membrane of the cheek, the alveolar processes of the upper jaw, the tonsils, fauces, parotid, and lower lip. These glands may become infected alone, especially with tuberculosis, but their clinical importance consists in the fact that metastases of carcinomas may occur in them. These results are based on a study of 87 cases, fifteen of them new ones, from v. Brunn's clinic. [J.E.S.]

The Virulence of the Bacillus of Bovine and Human Tuberculosis for Monkeys.—MacFadyen⁴ fed tuberculous udders and human sputum to 15 monkeys. Some of the animals died after from 2 to 10 days, probably of intoxication with the toxic products of the sputum. The remainder of the animals died after from 1 to 2 months of general tuberculosis. In all the animals fed with sputum, tuberculosis of the intestines was found, which was absent from all the rest. [J.E.S.]

Etiology and Pathogenesis of Aortic Aneurysm.—H. Arnspurger⁵ separates aneurysm of the aorta pathologically from aneurysm of other vessels on account of differences in dimension, function, position, and structure. A congenital form must be recognized, due to congenital stenosis of the isthmus. Three further groups of causes for aortic aneurysm are recognized—traumatism, infections, and intoxications. The author believes that trauma, as an exclusive cause, plays an extremely small part in the etiology. The same is true of the acute infections, although rheumatism frequently does produce diffuse weakening of the arterial walls. The chronic infections, however, are much more important; these include syphilis, tuberculosis, and malaria, of which syphilis is by far the most frequent factor. Examination of the walls of an aortic aneurysm shows the pathologic condition to be very similar to that found in syphilitic aortic disease. The conclusion is reached that syphilitic aortitis is the usual forerunner of aneurysm. Among the intoxications, alcohol, tobacco, and lead are noted for their influence in producing degeneration of the bloodvessels. Such diffuse degeneration may lead to dilation of the aorta, but will probably not play a part in the production of saccular aneurysm. [B.K.]

Antiseptic and Germicidal Properties of Glycerin.—M. J. Rosenau¹ gives the results of extended experiments made to determine the antiseptic and germicidal properties of glycerin. On account of the universal practice of using glycerin in the preparation of vaccine virus and the great importance of tetanus as a contaminator of that material, special studies were made to determine the effect of glycerin upon the spores of this organism. The results show that glycerin has distinct but feeble germicidal and bactericidal antiseptic properties. The presence of 50% of this substance will restrain all bacterial growth. Less than this amount cannot be depended upon for the preservation of vaccines and other organic growths. As a germicide, glycerin probably acts by virtue of its great affinity for water, abstracting this substance from the germ. Glycerin seems to have been a selective poison for *B. diphtheria*, which in all the experiments died much more quickly than any of the other organisms tested. The experiments proved that glycerin cannot be depended upon to purify vaccine or other organic material containing tetanus spores, and that it has practically no effect upon tetanus toxin. [A.G.E.]

Possible Origin de novo of Bacteria.—H. C. Bastian² brings forth arguments in an attempt to prove that organisms may originate independent of preexisting organisms of like kind. He claims that under certain general or local conditions in the body the common microorganisms may be converted into the so-called specific or pathogenic organisms. For example, Davaine's septicemia may originate in a previously healthy animal by the injection of putrid blood into the subcutaneous tissues and may become so virulent that a minute quantity of the animal's blood may transmit the disease. By injection into the peritoneal cavity the same putrid blood will produce a different and much less virulent disease, Pasteur's septicemia. The latter may also be induced by a germ-free chemic irritant. In this case the organisms arise either by heterogenesis or by the waking up of latent germs. There is also proof to show that the typhoid bacillus may be merely an altered and virulent form of the common colon bacillus. The author claims that, as good hygienic conditions will cure tuberculosis, low vitality and bad hygienic conditions may suffice to produce it. The commonly accepted channels of entry of the tubercle bacillus will not account for its isolated presence in the glands of the axilla, the hip-joint, etc. The bacillus of tuberculosis may be a product, and not a cause, of certain inflammations occurring in lowly vitalized subjects. The bacillus of leprosy may also arise *de novo*; and the investigations of Hutchinson concerning the influence of tainted fish in the production of this disease, are considered by the author to be potent arguments in favor of his contention. [B.K.]

Detection of Bile Pigments in Urine.—A. Jolles³ publishes an improved modification of his method for the detection of bile pigments in the urine. It consists of shaking 10 cc. urine with 2 cc. or 3 cc. chloroform and 1 cc. of a 10% barium chlorid solution. The mixture is centrifugated and the supernatant liquid poured off. The remaining chloroform and precipitate are washed 1 to 3 times with distilled water, then shaken with 5 cc. alcohol, 2 or 3 drops of an iodine solution added, and filtered. The filtrate shows a characteristic green coloration in the presence of the minutest trace of bile pigment. The reaction may be hastened by placing the mixture before filtration over a water bath for a few minutes. The iodine solution is prepared by dissolving separately 0.63 gm. iodine and 0.75 gm. mercuric chlorid in 125 cc. alcohol, combining them, and adding 250 cc. concentrated hydrochloric acid. It must be kept in a dark bottle. [B.K.]

Pathology of Cutaneous Burns.—G. Scagliosi⁴ scalded a number of rabbits, killed them after various intervals, and details the microscopic findings of the individual organs minutely. The central nervous system shows hyperemia and degeneration of Nissl's cells; the peripheral nerves show various grades of neuritis; the heart shows acute myocarditis; the liver acute parenchymatous hepatitis and necrotic foci; the kidneys

acute nephritis; the bloodvessels show proliferation of the connective tissue cells within 6 hours, and after 36 hours necrotic foci. The latter changes are due to the action of bacteria and their toxins as well as to changes in the chemic composition of the blood. The changes in the nervous system are produced by reflex irritation, insufficient nutrition and action on the part of the cells to the toxins circulating in the blood. Bacteria are deposited secondarily in the tissues and form new toxins; the liver and kidney changes also react on the nerve-cells, as their functions are more or less inhibited by the lesions. The parenchymatous changes are due to bacteria and their toxins. [E.L.]

The Tonsils and the Uvula in Tuberculous Patients.—Escome!¹ has examined the tonsils and the uvula in 25 tuberculous and in 21 nontuberculous cases. He concludes that the tuberculous infection of the tonsils is very common, and occurs as well in adults with no lung lesions; it cannot be found in most instances by macroscopic examination of the surface or of sections of the tonsil, but can be readily found with the microscope. The infection of the uvula is very rare. He has no doubt that the tonsils are the portal of infection in a very large number of cases of glandular tuberculosis, and of tuberculosis of the lungs; the infection proceeds from the tonsils most frequently by way of the lymph channels. [B.K.]

Relation of the Status Lymphaticus to Sudden Death, Death under Anesthesia, and to Infection.—G. Blumer² concludes from the study of 9 cases and a study of the available literature that: 1. The condition known as the status lymphaticus is a definite pathologic entity. 2. It is probably associated with, if not due to, a condition of intermittent lymphotoxemia. 3. It may be associated with sudden death, probably as a result of lymphotoxemia alone in some cases, or a result of the action of toxic, physical, or psychic injuries, which are rendered much more powerful than usual by the predisposing action of the lymphotoxemia. 4. In some cases the sudden death is undoubtedly mechanical and due to asphyxia from pressure of the enlarged thymus on the trachea. 5. The subjects of the status lymphaticus can be recognized clinically in some instances. [A.G.E.]

Hereditary Dwarfism; Ethnic Achondroplasia.—A. Poncet and R. Leriche³ distinguish 2 classes of dwarfism, one the pathologic dwarf, due to more or less definite skeletal lesions; and the other the essential dwarf, possessing a normal skeleton of diminished size. The latter is of the type which occurred in the ancient race of pygmies, and the authors believe the modern examples to be an atavistic reversion to that type. They report 2 cases from the same family, in which the dwarfish tendency was evidently inherited from the paternal side. Apart from their small stature, these 2 dwarfs were perfectly normal, and quite intelligent. Radiographic examination of their extremities showed that the epiphyseal cartilages were entirely wanting. The hereditary character of the dwarfism, with the absence of all evidences of a pathologic achondroplasia, led the authors to designate the condition "ethnic achondroplasia." Concerning the existence in ancient times of a race of pygmies, there can be little doubt. Their extinction was probably due to an evolution toward a superior type. Examples of dwarfism, such as have been cited by the authors, doubtless form a reversion to this variation of the human species. [B.K.]

Aspergillus Infection of the Lung.—H. Nakayama⁴ reports a case in which the diagnosis during life was bilateral lobular pneumonia, in a man 71 years old. At autopsy there were discovered, among other lesions, two small colonies of aspergillus bronchialis. The growth of mold had taken place in the necrotic walls of an old hemorrhagic infarct. In the center of the growth were found necrotic bronchi, through the walls of which the mold had spread. The aspergillus bronchialis is a new species, which was first discovered in man and described by Blumentritt, in 1900. The aspergillosis is a process secondary to the hemorrhagic infarct, the mode of infection being through the bronchi. [B.K.]

Syphilis of the Peripheral Nerves and Lungs.—C. M. Remsen¹ relates the case of a negro of 27, who died with symptoms of pulmonary tuberculosis. Repeated examination of the sputum had failed to disclose tubercle bacilli, and a microscopic study of sections of the lung showed neither tubercles nor tubercle bacilli. The lesions in the lung were predominantly those of the diffuse syphilitic consolidation described by Councilman, with definite areas of caseation, organization of part of the exudate, and induration of the lung by newgrowth of interstitial tissue. The occurrence of cavity formation by the disintegration of the caseous tissue, with erosion of a vessel and fatal hemorrhage, is of especial interest. The involved nerves contained no evidence of tuberculous infection, but had every character of a syphilitic neuritis with caseation of the new-formed tissue and nerves. [A.G.E.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 15, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	Fresno.....Dec. 1-31.....	2

Changes in the Medical Corps of the U. S. Navy for the week ended January 16, 1904:

CRANDALL, R. P., surgeon, detached from the Naval Station, Guam, and ordered to the Wisconsin—January 12.
MURPHY, J. A., passed assistant surgeon, commissioned a passed assistant surgeon from March 3, 1903—January 14.
Doctors R. C. Heiner and R. E. Stoops, appointed assistant surgeons with rank of lieutenant, junior grade, from December 26, 1903—January 14.

Changes in the Public Health and Marine-Hospital Service for the week ended January 14, 1904:

WHITE, J. H., surgeon, granted leave of absence for seven days from January 11—January 9, 1904.
GUITERAS, G. M., surgeon, detailed as inspector of unseviceable property at Havana, Cuba—January 12, 1904.
WICKES, H. W., passed assistant surgeon, granted leave of absence for two days from January 16—January 14, 1904.
GRUBBS, S. B., passed assistant surgeon, granted leave of absence for ten days—January 8, 1904.
AMESSE, J. W., assistant surgeon, granted extension of leave on account of sickness, for ten days from January 11—January 9, 1904.
DUKE, B. F., acting assistant surgeon, granted leave of absence for five days from January 14—January 14, 1904.
TIDD, R. M., acting assistant surgeon, granted leave of absence for seven days, under paragraph 210 of the regulations.
TUTTLE, JAY, acting assistant surgeon, department letter granting Acting Assistant Surgeon Tuttle leave of absence for ten days from December 21, 1903, amended to read five days from December 21, 1903—January 9, 1904.
WALKER, R. T., acting assistant surgeon, granted leave of absence for twenty days from January 5—January 9, 1904.
MAGUIRE, E. S., pharmacist, granted extension of leave of absence for ten days from January 8—January 12, 1904.
RICHARDSON, S. W., pharmacist, to proceed to New York, N. Y., for special temporary duty—January 9, 1904.

Changes in the Medical Corps of the U. S. Army for the week ended January 16, 1904:

MARRY, WILLIAM C., contract surgeon, is relieved from duty at Columbus Barracks, and will proceed to Fort Sheridan for duty.
BROWN, HENRY L., contract surgeon, now on temporary duty at Columbus Barracks, is assigned to station at that post.
CHAMBERLAIN, Captain WESTON P., assistant surgeon, is relieved from duty in the department of the East, to take effect upon the withdrawal of troops from Cabana Barracks, Cuba, and upon his arrival in the United States will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands on transport to sail from San Francisco about March 1.
BEVANS, First Lieutenant JAMES L., assistant surgeon, upon the withdrawal of troops from Morro Castle, Santiago, Cuba, will upon his arrival in the United States proceed to Fort Barrancas for duty to relieve First Lieutenant Reynold M. Kirby-Smith, assistant surgeon. Lieutenant Kirby-Smith will proceed to San Francisco and report for transportation to the Philippine Islands on transport to sail from San Francisco about March 1.
STEARNS, CHARLES H., contract surgeon, now at Nevada, Mo., is relieved from further duty in the division of the Philippines, and upon the expiration of his present leave will proceed to Fort Monroe for duty, to relieve First Lieutenant Haywood S. Hansell, assistant surgeon. Lieutenant Hansell will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands on transport to sail from San Francisco about February 1.
CORBUSIER, HAROLD D., contract surgeon, now on temporary duty at Fort Mansfield, is relieved from further duty at Fort Columbus, and will report at Fort Mansfield for permanent duty at that post.
IVES, Major FRANCIS J., leave for seven days granted is extended twenty-three days.
HUTTON, First Lieutenant, PAUL C., is granted leave for one month on account of sickness.
The following changes in the stations and duties of officers are ordered: So much of paragraph one, October 13, 1903, as relate to James W. Van Dusen, assistant surgeon, is revoked. Lieutenant Van Dusen is relieved from duty at Columbus Barracks, to take effect upon the expiration of his present sick leave, and will then proceed to West Point, N. Y., and report in person to the superintendent of the U. S. Military Academy for duty not later than January 20, to relieve Captain Alexander N. Stark, assistant surgeon. Captain Stark will repair to Washington, D. C., and report to the surgeon-general of the Army for duty as assistant to the attending surgeon in that city until April 1, when he will relieve Major William B. Banister, surgeon, from further duty as attending surgeon. Major Banister will proceed to Jefferson Barracks for duty.
BRANCH, FREDERICK D., contract surgeon, is granted leave for one month, from about January 26.
GREGORY, WILLIAM G., contract surgeon, is relieved from duty at Fort Apache, and will proceed to his home, Cave in Rock, Ill., for annulment of contract.
GREGORY, WILLIAM G., contract surgeon, is granted leave for one month.
BROWN, CLARK L., sergeant first class Fort Monroe, will proceed at once to St. Louis, Mo., and report to Major Richard W. Johnson, surgeon, in charge of the medical department exhibit, Louisiana Purchase Exposition, in that city, for duty.
BAIGENT, JOHN, sergeant first class, upon arrival in the United States with troops from Morro Castle, Santiago, Cuba, will proceed to Fort Monroe for duty.

VOL. VII, No. 5.

JANUARY 30, 1904.

\$5.00 YEARLY.

Union in New York at Last Realized.—Just as we are going to press we receive a telegram from Dr. McCormack, at Albany, bringing the news of the unanimous adoption of the report of the joint committee and the agreement for the consolidation of the Society and Association, including a constitution and by-laws. The committee was continued to complete the details of the union. The permissive act has been passed by the State Legislature and approved by the Governor. The adoption of the resolution was moved by Dr. Jacobi, and seconded by Dr. Roosa and Dr. Potter. Thus is finally ended the unfortunate division of the New York profession, and the greatest step is made toward the union and reorganization of the entire body of American medical men. The vast influence of this act for the good, both of the profession and of the entire people, cannot be estimated, at present not even conceived. The American Medical Association is now called upon to assume its destined role, to shape and bring about legislation, to reduce the evils of quackery and greed, both within and without its ranks, to realize the possible lessening of the deathrate by hygiene and preventive medicine, to encourage pure science, and to band all honorable physicians into a mighty force for promoting the national health and well-being.

Good Roads and the Country Doctor.—There is now pending in Congress a bill which appropriates \$24,000,000 as national aid for the building of wagon roads. This money is to be distributed according to the population of each of the States, except that the States having less than 700,000 people are to receive a minimum amount of \$250,000. Each State, county, or town receiving national aid must add a like amount. This bill will result in the spending of \$48,000,000 for the building of wagon roads, and will build from 100 to 500 miles of road in every State of the union. Every physician of the nation is directly interested in good roads. The lives of country physicians are made harder and shorter because of the bad roads, which are everywhere the rule. Even the city consultant has occasionally to realize personally how they add to the wear and tear of life. Four of our States (New Jersey, Connecticut, Massachusetts, and New York) have appropriated over \$16,000,000 for 2,418 miles of roads. The United States Government appropriated in 1903, \$32,000,000 for river and harbor improve-

ments, but nothing for good roads for the farmer. France has 23,608 miles of good wagon roads, Italy 5,000 miles, etc. Every consideration of health, civilization, and justice demands good country roads for the people. Hon. Walter P. Brownlow, member of Congress, will upon application send pamphlets to any address in illustration of the wisdom and benefit to be derived from the passage of the proposed bill. The members of our profession, both for public as well as for medical reasons, should unite in helping to make it a law. We should write our representatives at Washington, urging them to vote for the measure.

"No blacker stain on the civilization of the nation" exists, says an expert, than the sufferings of the animals in some of our Western States. They are turned out to freeze, hunger, and thirst for the winter, and hundreds of thousands endure greater agonies in one day than all the animals of eastern cities in a year. Enough will survive to make a profit for the comfortably-housed capitalists and trust-owners. All this time, if in a laboratory an animal is subjected to the prick of a hypodermic needle there is a howl of horror from all the science-hating antivivisectionists of two continents. In some States the owners of the tortured cattle have prevented the enactment of laws for their care, on the avowed ground that it would be bad for their business. "On one single ranch in Texas last winter," says Superintendent Whitehead, "\$500,000 worth of cattle died. On many ranches half were lost; on some, three-quarters; on almost all, many; while all the rest went down to the very verge of death, and suffered all its pain without its relief." Can anyone explain why a hundred forms of frightful cruelty, when committed for commercial profit, do not interest antivivisectionists, while a needle-prick in the cause of medical science arouses a violence of rage that is uncontrollable?

The passage of the Hepburn Pure Food Bill by Congress brings about one of the greatest possibilities of reform of the alarming conditions into which our people had fallen. Few knew or realized the extent to which adulteration and fraud in the manufacture of foods were practised. The most necessary articles of diet were debased and the only caution observed in the

infamy was that the criminals should not be found out. The injury to health from the use of their products did not apparently disturb the manufacturers any more than their own cheatings. The bill just passed, fixes the standards of foods and drugs as to their purity, strength and character and defines what shall be considered adulterations or misbranding of foods and drugs. It also prohibits interstate commerce in or importation and exportation of such misbranded or adulterated articles. It is proposed to enlarge the scope of the Bureau of Chemistry to include the Bureau of Foods, and impose upon it the duty of performing all chemic work for the other legislative departments. This bureau will be charged with the duty of inspecting food and drug products which belong to interstate or foreign commerce. The Secretary of Agriculture is given authority to employ such chemists, inspectors, clerks and laborers as may be necessary for the enforcement of the act. One section of the bill provides penalties for the introduction of adulterated or misbranded foods or drugs and another section requires the Secretary of Agriculture to prescribe rules and regulations to govern the Director of the Bureau of Chemistry and Foods in examinations of articles required to be inspected under the law. The whisky and liquor manufacturers, of course, are violent opponents of the bill—a fact that constitutes a good argument for it.

The Pennsylvania Society for the Prevention of Tuberculosis.—The report of this society, just issued, will give encouragement to all its members. The organization was the first of its kind in America, if not in the world, having been founded in 1892, by Dr. Flick, the present director of the Henry Phipps Institute. The present report is issued by its president, Dr. Howard S. Anders. From it one learns with regret of the failure, only temporary, let us hope, of the work of the society in trying to secure from the State Legislature the passage of a bill for the establishment of two State sanatoriums for poor tuberculosis patients. The politicians were found too indifferent to the matter, and too engaged in their own schemes to give any attention to this duty and interest of the people. In another direction the society's efforts should be more earnestly seconded to break up the wretched vogue of the quack tuberculosis cures. The report says that "legislation against these heartless, commercialistic triflers with the credulous and hopeful tuberculosis patient is sorely needed. The rude awakening and despair which the uniform failure of these nostrums to cure produces, operates sadly in causing patients to neglect or decline rational regimen and treatment, since they incline to think that if the much-testimonialized medicine does no good, there can be no use in trying further aid." Physicians of the State can aid the work of the society in a practical manner by becoming the distributing agents among patients, of the following tracts, issued by the society:

Tract No. 1.—How to Avoid Contracting Tuberculosis (Consumption).

Tract No. 2.—How Persons Suffering from Tuberculosis Can Avoid Giving the Disease to Others.

Tract No. 3.—How Hotel Keepers Can Aid in Preventing the Spread of Tuberculosis.

Tract No. 4.—How Storekeepers and Manufacturers Can Help to Prevent the Spread of Tuberculosis.

Tract No. 5.—Predisposing Causes of Tuberculosis, and How to Avoid or Overcome Them. (Printed also in Hebrew.)

Tract No. 6.—Registration of Tuberculosis.

"Above all Things, no Zeal!"—In reaction against zealotry in the promulgation of medical discovery and truth there is the caution of a wise restraint which is necessary and good—if it is based upon clinical facts, and not upon prejudice and vanity. But there is often a vanity as pernicious as that of the zealot in those who cry out against him and his "exaggeration" solely from policy, from avoiding extremes, and from the self-flattery that the rational and intellectual critic has a superior judgment and a better poise of mind. Careful choosing the middle or average truth in order to avoid the dangers of extremes, and utter recklessness as to the real facts, may be simply the cunning coward's way. Adding extremes together and striking the average never discovered any truth, or, in fact, anything in the world—not even the inaptitude of the averager. When Pasteur was making the most profound and revolutionary discovery of modern medicine, the great surgeon, Chassaignac, warned him that "everything could not be resolved into bacteria," and that his conclusions should be brought out "in a circumspect, modest, and reserved manner." These words were true enough as an abstract statement, but their real untruth and their special inapplication to the case in hand could never be known by the *surtout pas de zèle* Chassaignacs. The noteworthy fact about the Chassaignacs is that they are more interested in hitting the "exaggerator" over the head than in investigating his "little and partial truth," and finding out how far it will carry. That is to say, they are more concerned about their own standpoints and prejudices than about any truth, least of all the little one they ignore.

Carbuncle Contracted in the Barber Shop.—The transference to his customers, by means of his hands and instruments, of many parasitic skin diseases has long been recognized as one of the unnecessary accomplishments of the necessary barber. Among these affections are sycosis, impetigo, seborrheic alopecia, and furunculosis that is more or less chronic in type. Dr. Graham Chambers states that during the past five years impetigo circinata has been very prevalent in Toronto, scarcely a month passing without an outbreak of from two to thirty cases, generally traceable to a common source. The barber shop is so commonly the source that he designates the disease as "barbers' impetigo." Quite recently Dr. W. A. Hardaway has called attention to a point which he believes, and we think rightly, has been but little realized by the medical profession. That is the frequency with which carbuncles are acquired in barber shops. He has seen many cases of carbuncle in which the evidence of this means of transmission was to him indisputable. The relative importance of this serious affection as compared with the other diseases mentioned needs scarcely to be impressed. For the prevention of contagion in barber shops, Hardaway believes that we will be forced to rely upon an educated

public opinion rather than upon compulsory laws directed against the barber. He recommends that each patron of a barber shop provide himself with a box, containing his own brush and comb, a small package of absorbent cotton, and a 5% carbolic acid solution. The barber will then wipe his shears or clippers with the solution, and use the patron's comb and brush. For the man who shaves, his own soap, cup, and brush are necessities. These suggestions are sensible. To carry them out properly means some inconvenience, but it is worth while, especially to the aged and debilitated, or to those suffering from diabetes or similar diathesis. Physicians attending such patients should extend to them a warning in this regard.

The alarming increase of cocaineomania is not recognized nor the seriousness of the crime correctly estimated. Every druggist, if questioned closely, will admit the evil, and rightly or wrongly will lay the blame upon others. The number of nostrums and "patent" medicines containing the drug is increasing, and with one excuse or another, every one who wishes it can readily obtain it. A prominent physician from one of the southern States has stated that although its sale, except upon a physician's prescription, is illegal, many drug stores openly sell hundreds of ten-cent packages every day. The negroes by thousands are being ruined by the abuse, which is becoming a racial and a national problem. The more poor wretches there are who are thus reduced to destitution and degradation, the greater the expense to the community, and the more impossible becomes the solution of sociologic problems. The social wrecks and derelicts made by this illegal and criminal traffic must be cared for by the public, and hence the duty and the self-interest become imperative that for a petty profit these criminal druggists shall not be allowed to create the pitiful victims which must then be supported by the charitable, the city, or the State, until they die. One remedy for the scandal, which in other things has proved effective, is for the local Boards of Health to secure the easily obtained evidence of the illegal sales, and then to prosecute the shameless druggists to the full extent of the law. An aroused public sentiment is necessary for the extinction of the infamy.

Changing the form of medical words established by usage in order to make them conform to some supposed demand of etymology, is a dangerous and useless thing to attempt. It seems especially to afflict the ophthalmologists. Some years ago a heroic war was made upon the words *hemeralopia* and *nyctalopia*, with the object of reversing or exchanging their meanings. The result was the banishment of the words from the writing of any one who wished to be understood. Luckily they were not needed, and their death was desirable, and the artificial respirationists served in the excellent capacity of embalmers. The oculists are again hammering at one of their most used words, *astigmatism*, endeavoring to change it to *astigmia*, and as before, in the interest of etymology. One may have all the sympathy in the world for the scholarship and motive, and still smile at the futility of the attempt. A man of fifty may get the

Legislature to change his name, but unless he disappears from the places where he is known, he will hardly succeed in his attempt, and he will probably make failure ridiculous. But a word cannot leave all the places where it has been domiciled. Moreover, when looked into closely, the supposed interests of etymology are factitious and fictitious. The dictionaries will attend to the origin and histories of words; in our daily writing and speech we can pay no attention to etymologies. Those who would rechristen a few old words cannot succeed, and in almost all the other words of the language, they do not care a fig for etymology and history. There is hardly a word they use in daily speech and writing that would not have to be made over or its use discontinued if they carried out their principles. History and philologic evolution are utterly reckless of etymology and of scholastic principles. Every living word is constantly changing in spirit or meaning. Would the rechristeners and worshipers of etymology compel us to understand by the word *idiot* simply a *private* as distinguished from a *public* person? Does a *candidate* now dress in *white*? Is a *sincere* person one without wax? Would they lead *tarsus*, *carpus*, *thyroid*, *fornix*—any word of our hundred thousand—back to its original forms and meanings? It is impossible, and will end in failure. It is true that in forming a new word the coiner should be most careful about his designs and dies, but once coined, the word cannot be restamped without an utter remelting. To restamp the made coin with a new die would be crazy numismatics, would at least make numismatists crazy. The new-old coin would be very curious, perhaps, but wholly useless. Any form of word once accepted to denote astigmatism is understood, and should be left in peace. Almost all these modern scientific and medical terms were, in fact, not derived from the Greek roots. They were only said to have been derived, so that the attempt to change one form of an accepted word for another is merely to give a foundling the name of one assumed father instead of another which he has also falsely borne. It is most noteworthy in all these discussions that those who represent themselves so deeply reverent of etymology as to a few foundling words, are utterly indifferent to two greater classes of words, whose parents were really married: 1. The great mass of historically transmitted from classic sources, but changed in form and meaning from what they were in primitive times. 2. The Teutonic or Anglosaxon words which form the backbone of the language, about whose origin and history the pseudoclassic scholar is as ignorant as he is indifferent. Their spellings and meanings are also subject to the same false logic and criticism as in the case of *astigmatism*, etc. Fortunately they are too solidly settled to arouse useless and absurd controversy.

Care of the Discharges of Typhoid Fever Patients.—Moved by the sad experience of other cities as to contaminated drinking water the Wilmington, Del., Water Department has issued an admirable card for general distribution to the attendants of patients. It is herewith reproduced "for the benefit of all whom it may concern."

Typhoid fever is caused by a germ which finds its way into the food or, more frequently, the drinking water.

The germ causing typhoid fever is *invariably* derived from the stools and urine of persons suffering from the disease.

The disease may be also communicated through soiling one's hands with the discharges and then permitting the hands thus soiled to come in contact with the food.

Infection may be prevented by destroying the germs in the discharges by means of disinfectants.

Therefore, to save yourself as well as others from infection, observe the following precautions:

1. Keep on hand a 5-gallon jug or other suitable vessel filled with any one of the following solutions:

SOLUTION No. 1.—Chlorid of lime of the best quality, guaranteed to contain at least 25% of available chlorin and free from a strong odor on opening the box, 8 ounces to each gallon of water.

SOLUTION No. 2.—Formalin (40%) 5 fluid ounces to each gallon or a little over 1½ pints to the 5 gallons of water.

SOLUTION No. 3.—Carbolic acid 4 ounces to the gallon or 1½ pints to the 5 gallons of water.

The choice of any of these solutions should be determined by the ability to obtain the pure article. Whatever solution is used the vessel should be kept tightly corked.

2. Have the receptacles for the stools (bed-pan, night-chamber, etc.) provided with a closely fitting lid, or improvise a lid from several thicknesses of paper with some weight over it. It is better to have two receptacles of a kind so that a clean one may be always on hand for the patient's use.

3. When required for use, put 1 pint (2 glassfuls) of the disinfectant into the vessel (or if the urinal is used, a quarter of a pint) so that the discharges may come in contact with the disinfectant on their very issue from the body. No harm is done if some of the disinfectant should happen to spill on the bed-clothes.

4. Remove the vessel containing the discharges to some secluded place in the house, add enough of the disinfectant to completely cover the discharges, stir up the contents with a small stick, replace the lid and allow it to stand for at least two hours. Remember that the longer you permit the discharges to come in contact with the disinfectant the more harmless do they become and the less obnoxious to handle.

5. If there is no water-closet in the house, the discharges, after the disinfection, should be buried in the soil at least 100 feet from any well or stream.

6. When your hands become soiled with the discharges, they should be washed, first in the disinfectant (neither of the disinfectants will injure the skin) and then with soap and water.

7. All articles of the patient's clothing which have become soiled, and all the sheets, towels, napkins, etc., used by the patient should be kept in Solution No. 2 or 3 (not in Solution No. 1) until they are washed.

8. Use the disinfectant freely on all occasions requiring cleansing of soiled surfaces, and remember that "an ounce of prevention is worth a pound of cure."

Additional Prize Awarded.—The Osiris prize of \$20,000 has been divided between Mme. Curie and Dr. Edward Branly, the former receiving \$12,000 and the latter \$8,000. Mme. Curie first began the researches on polonium and radium. A study of uranic radiation by M. Becquerel had led her to these investigations. Her husband, finding her studies intensely interesting, helped her in her experiments, and thus together they discovered the properties of radium. The second part of the Osiris prize is awarded to Dr. Edward Branly. The French consider him the real inventor of wireless telegraphy, though they do not deny that Marconi was the first to practically apply it. He is the author of numerous scientific works, and is a practising physician. This Osiris prize, valued at \$20,000, was placed in the hands of a committee of the Parisian press as early as 1897, to recompense the greatest invention and greatest humanitarian work exhibited at the Exposition of 1900. The committee failing to find anything that merited it, has held it until now. Mr. Osiris pointed out that Mme. Curie, having the greater part in the discovery, merited a separate reward. Dr. Roux, of the Pasteur Institute, won the institute's \$8,000 Osiris prize this year, refusing it for himself, but accepting it for the institution.

AMERICAN NEWS AND NOTES.

GENERAL.

Bequests to Charity.—PHILADELPHIA: By the will of Harriet Richards, \$46,500 is left to various Catholic institutions, mostly in Philadelphia. By the will of Conrad B. Day, \$4,000 is left to public institutions in Philadelphia.—BALTIMORE: By the will of John Q. A. Holloway, \$9,100 is left to Catholic institutions, mostly in Baltimore.

To Display Antispitting Ordinance.—The Health Department of Baltimore has had 50,000 cards printed calling attention to the law prohibiting spitting on the floors of street cars and in public buildings. These cards will be distributed among car conductors and custodians of public buildings for proper display. Health Commissioner Bosley says he wants the public to know that there is an antispitting law and that the cards will act as a deterrent of the spitting habit.

Pure Food Bill Passed the House.—The House of Representatives has passed the pure food bill by a vote of 201 to 68. The amendment, inserting the word "willful" with reference to persons who sell adulterated or misbranded goods, and which would have compelled the Government to prove intent to violate the law by the vendors, was stricken out on a yeas and nays vote in the House. The bill fixes the standards of foods and drugs as to their purity, strength, and character, and defines what shall be considered adulterations or misbranding of foods and drugs. It also prohibits interstate commerce in or importation and exportation of such misbranded or adulterated articles.

Examination for Medical Clerk.—The United States Civil Service Commission announces an examination on February 17-18, 1904, at many places in the United States to secure eligibles from which to make certification to fill 18 vacancies in the position of copyist (male), at \$900 per annum, in the Bureau of Pensions, and other similar vacancies as they may occur. Age limit, 25 to 30 years. Only graduates of recognized medical schools may be examined. This examination is held to establish a register of eligibles with a knowledge of medicine, and is open to all citizens of the United States who comply with the requirements. Competitors will be rated without regard to any consideration other than the qualifications shown in their examination papers, and eligibles will be certified strictly in accordance with the civil service law and rules. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C.

Miscellaneous.—DR. YAMEI KIN, the first Chinese woman to take a medical degree in the United States, is on a visit to this country from her home in Ning-Po, where she was born. Dr. Yamei graduated from the New York Medical College about 10 years ago. Then she returned to China, where she practised medicine. The doctor, who is highly educated and well versed in languages, is an earnest worker in the cause of uplifting her fellow countrywomen. She will remain in America for a year or more.—PHILADELPHIA: Dr. THOS. G. ASHTON has been elected professor of clinical medicine in the Polyclinic Hospital to succeed Dr. Judson Daland, resigned. After February 1, Dr. Guy Hinsdale will practise at Hot Springs, Va.—"INTERNATIONAL MEDICAL JOURNAL": It is reported this journal will cease publication with the issue for January, having been consolidated with the *Archives of Pediatrics*. Both journals have been published by E. B. Treat & Co., of New York. The editorial and other management will be that at present in charge of the *Archives of Pediatrics*.—"INTERNATIONAL MEDICAL JOURNAL": The January number of this journal contains a critical review of the progress of medicine during the year 1903. The subjects of internal medicine, surgery, therapeutics, pathology, bacteriology, gynecology and obstetrics, pediatrics, orthopedics, neurology, genitourinary surgery, dermatology and syphilis, laryngology and otology, and ophthalmology are each taken up and reviewed critically, and the important discoveries and advancements of the year are interpreted and presented in a readable light. This represents a somewhat unusual variety in medical journalism—one which is commendable and instructive and interesting to the profession.—UNIVERSITY OF PENNSYLVANIA: At the December meeting of the trustees of the University of Pennsylvania the following physicians received appointments: Fred. M. Paul appointed assistant demonstrator of anatomy and prosector to the associate professor of applied anatomy; H. B. Aliyn, Bernard Kohn and Joseph Evans, instructors in medicine; R. Max Goepf, instructor in physical diagnosis. At the November meeting the following appointments were made: E. Hollingsworth Siter, instructor in genitourinary diseases; Albert P. Francine, instructor in clinical medicine; Chas. H. Hatfield, instructor in medicine; Tasker Howard, assistant demonstrator of physiology; Walter S. Cornell, assistant demonstrator of anatomy; Frank A. Craig, assistant demonstrator in medicine; Leo Loeb, William T. Cummins, and Henry R. Alburger, assistant demonstrators of pathology.—"THE JOURNAL OF INFECTIOUS DISEASES": The first number of this new journal is dated January 2, 1904. As understood, the purpose of this journal is to be

confined exclusively to investigations relative to the infectious diseases. It will not be published regularly, but at such times as is deemed wise by those in charge. The journal is unique in being the only endowed medical journal in the United States. The present number consists of more than 200 pages, and contains a number of scientific and valuable articles.—**BULLETIN OF THE AYER CLINICAL LABORATORY:** The first number of this Bulletin just issued is dated October, 1903. It is the result of the deep interest taken in the promotion of the laboratory by the late Dr. Thomas G. Morton, and the generosity of Frederick Fanning Ayer. Succeeding numbers will be issued as valuable scientific material is accumulated. Dr. Simon Flexner announces that the Bulletin will be sent to those making request for it. It is issued from the laboratory of the Pennsylvania Hospital, Philadelphia.

EASTERN STATES.

Health and Changed Methods of Living.—It seems that all the means once reckoned upon as sure to invite colds will have to be considered as obsolete as are the heroic remedies for these afflictions that our grandmothers used. Once it would have been thought extremely imprudent to wash even the face in cold water on a winter morning, and here we are, all of us, taking icy baths, sponge, plunge, or shower, every morning of our lives as a means of keeping ourselves free of colds, and in a generally healthy trim. Nowadays, there are all the boys and girls who go bareheaded and don't know what a "violent cold" is, and the persons who sleep out of doors and boast of it, and the army of folk of all ages who will have none of the heavy clothing, to show that the ideas of our ancestors on the matter of "getting cold"—all of them, except rare Ben Franklin, who held precisely the views of today—were all fudge. We wonder what the attitude of those who compose the generation 3 times removed from the present one will be on the subject of colds.—[Editorial, *Boston Transcript*.]

Public Health in the Philippine Islands.—According to the *Boston Transcript*, 2 significant facts are brought out in the report of the Board of Health for the Philippine Islands for last July. One is that the public health should not be placed in the hands of the local Filipino authorities for administration, and the other is that the climate is not so severe upon the Americans as has been generally understood in this country. The deathrate in Manila in July is remarkably high, varying from 37.88 per thousand in 1900 to 107.02 in 1902, and 83.21 last year. Yet the rate among Filipinos last year in July was 35.32 per thousand, and among Americans only 10.74. This high rate is largely due to the cholera, of which there were 24 cases in Manila last July, although only 1 was of an American. The cholera appeared near the source of Manila's water-supply, and threatened the city with an epidemic, as the local authorities paid little attention to it. The Americans promptly organized a sanitary service and quarantined the infected towns, stamping out the outbreak within 30 days. The difficult problem presented was handled with energy and discretion, 2 qualities which were noticeably absent in the local Filipino health officials. It is apparent, however, that the city of Manila needs some one to do for it the splendid sanitary work which was done for Havana by the late George A. Waring.

NEW YORK.

Cornell University Medical College.—The Faculty has inaugurated a new scheme in the lines of instruction given by the subordinate professors and their assistants, a number of whom are conducting more or less specialized lines of research in which they excel. In the department of general surgery, Professor Kammerer will lecture to students upon intestinal obstruction, and Professor A. B. Johnson upon the surgical disorders of the breast. In general medicine, Dr. Conner will take up the subject of the ductless glands, and Dr. Camac the practical aspects of infection and immunity. In general pathology, Professor Ewing will lecture upon the scientific mechanism of immunity. Dr. Schlapp will follow with a few lectures upon localization in the central nervous system, and Dr. Schultze will end the course with a few lectures upon cerebral hemorrhage.

Preventing Pneumonia.—The advisory board of the Department of Health has given out a statement, which, in part, is as follows: "The present increase in pneumonia of various types is a source of solicitude to those having the interest of the public health in charge, for it has been fully established that a certain proportion of cases of pneumonia are communicable and by proper care their spread may be prevented. The various forms of acute pneumonia which are now prevalent, both in adults and in children, are incited by bacteria. Exposure, cold, overexertion, lack of physical vigor, and abuse of the use of alcohol, predispose the individual to pneumonia, but are not its direct causes. The bacteria are usually conveyed in the dust of the air contaminated by sputum and nasal or other discharges. It is of urgent importance that the regulations of the Health Department for the suppression of the filthy and dangerous practice of spitting upon floors, pavements, or other unsuitable places should be rigorously enforced. Feather dusters should be abandoned and moist cloths used for dusting. When practicable sweeping should be done in the evening."

PHILADELPHIA, PENNSYLVANIA, ETC.

Hospital at Orange Quarantined.—Under orders from the Board of Health the Orange Memorial Hospital was placed under quarantine January 18, because of diphtheria in the institution. One of the rules of the hospital is that no contagious disease shall be received, but these cases developed in persons suffering from other illnesses.

Smallpox Increases in Philadelphia.—According to the report to the Bureau of Health, there were for the week 106 new cases, with 14 deaths, an increase of 44 cases and a decrease of 10 deaths, as compared with the preceding week. The week's returns establish a new record for the winter, the highest previous number for a week being 99 cases, in November.

Talks on School Hygiene.—Under the auspices of the Board of Education, a series of lectures on school hygiene are to be delivered by prominent physicians of Philadelphia. Dr. S. Weir Mitchell will deliver the first of this series and will discuss "Nervous Diseases, Their Causes and Effects." Later, during the winter and spring other lectures will be delivered on appropriate subjects by other physicians.

Typhoid Fever at Kittanning.—The State health authorities and the local Bureau of Health at Kittanning, Pa., are at loggerheads. On account of the prevalence of typhoid fever and the increasing number of new cases occurring daily the State representative had placards placed in the hotels, cafes and bars of the town warning the people against drinking the water from the taps. The local authorities ordered all the placards removed, which has been done.

Health Conditions in Pittsburg and Allegheny City.—Contagious diseases and deaths from same reported to the Pittsburg Bureau of Health for the 14 days ended January 9, 1904: Smallpox 36 cases and 8 deaths; diphtheria 35 cases and 10 deaths; scarlet fever 39 cases and 5 deaths; typhoid fever 200 cases and 23 deaths. There were 30 deaths from tuberculosis and 54 from pneumonia. Total deaths from all causes 348, in a population of about 354,000. Contagious diseases reported to the Allegheny Bureau of Health for the 14 days ended January 9, 1904: Smallpox 16 cases; diphtheria 44 cases; scarlet fever 15 cases; typhoid fever 18 cases.

The Noise of Trolley Cars.—An exchange says: "The health authorities in New York have rightly decided that the nerve-shattering thumping of the trolley cars caused by 'flat wheels,' is a subject calling for their intervention, and they have taken up the matter with the street railway corporation. It would be too much, perhaps, to say that every other car in Philadelphia is afflicted with this defect; but it is indisputable that the proportion is very large, and the evil is one which cries aloud for remedy every hour of the day and night. Those who live near the Rapid Transit lines can testify to this. Whether the subject calls for police regulation or for control by the Bureau of Health may be an open question; but no one will dispute the need for a remedy. Of course, to keep the car wheels in proper condition would mean expense to the companies; but, on the other hand, the wear and tear on the rails from the constant hammering would suggest the necessity for action without waiting for compulsion."

Milk Supply in Philadelphia.—Dr. Leonard Pearson, State Veterinarian, is reported as saying: "The great bulk of the milk at present being shipped into Philadelphia is wholesome enough, but notwithstanding the efforts of the inspectors, enough contaminated milk is sold here daily to destroy many lives. The reason is that the middleman, who is the dealer, seldom visits the farm where the milk which he distributes is produced, and in his dealings forces the farmer down to the last cent. I regret that we have no regular inspection of the dairies from which we receive our milk. One would naturally expect that the milk purchased by benevolent institutions like our hospitals would have been specially scrutinized, but when an inquiry was started, it was found that only 3 of our hospitals paid any attention to the purity of the milk they fed their patients. The others not only purchased the ordinary market milk, but the determining question as to who should be selected to supply it was the question of price. Through the efforts of the Health Bureau, all the hospitals are now using pure milk."

SOUTHERN STATES.

Bureau of Chemistry at Washington, D. C., to be Enlarged.—It is proposed to enlarge the scope of the Bureau of Chemistry to include the Bureau of Foods, and impose upon it the duty of performing all chemist work for the other legislative departments. This bureau will be charged with the duty of inspecting food and drug products which belong to interstate or foreign commerce. The Secretary of Agriculture is given authority to employ such chemists, inspectors, clerks and laborers as may be necessary for the enforcement of the act. One section of the bill provides penalties for the introduction of adulterated or misbranded foods or drugs and another section requires the Secretary of Agriculture to prescribe rules and regulations to govern the Director of the Bureau of Chemistry and Foods in examinations of articles required to be inspected under the law.

WESTERN STATES.

Typhoid Fever at Leadville.—It is reported that a serious epidemic of typhoid fever prevails at Leadville. There were 500 cases of the disease in Leadville on January 21. The situation is serious, not only because of the rapid spread of the disease in Leadville, but from the fact that there is danger of the Arkansas river becoming contaminated, which would jeopardize the health of thousands of persons along its banks.

Antitoxin Should be Made at the University.—The Bulletin of the Chicago Health Department says: "The earliest period at which relief can be afforded by the production of antitoxin at the State University—which would seem to be the proper agency—will not be much less than 4 months, but during this time all needed antitoxin for the treatment of diphtheria among the poor and destitute of the city will be provided in some way."

Prevention of Tuberculosis in Minneapolis.—Minneapolis is added to the cities leagued in active campaign against the ravages of tuberculosis. The base of operations will be the Department of the Associated Charities for the Prevention of Tuberculosis. The committee in charge of this department is just completing its organization, which is modeled somewhat on that of the similar committee of the New York Charity Organization Society.

Comparison with Reference to Tuberculosis.—The Bulletin of the Chicago Health Department says: "A comparison of the New York with the Chicago figures of deaths from pneumonia and tuberculosis up to January 2—date of the last New York report received—shows a close agreement as to pneumonia, but a wide difference as to tuberculosis. The pneumonia deaths formed 18.6% of the total mortality in Chicago and 18.7% in New York. On the other hand, while the tuberculosis deaths were 12.1% of the total deaths in New York, they were only 9.3% in Chicago. Chicago's deaths from tuberculosis were 30% less than New York's."

Inspection of Private Hospitals in Chicago.—The Bulletin of the Chicago Health Department says: "Another and more rigid inspection of private hospitals, with special reference to their precautions against fire, was begun during the week. The last previous inspection, in the spring of 1902, was made by the Building Department alone. The one now being made is under the joint direction of that Department and the Department of Health—a building inspector and a medical inspector working together in each investigation, and making joint reports to each Department. In this way it is hoped to secure better results in the matter of prompt remedy of defects discovered."

Infant Mortality in Chicago during 1903.—The Bulletin of the Chicago Health Department for the week ended January 2, says: "The disastrous effects on child life—threatened by the barbarous action of the milk-wagon drivers in refusing to make more than one delivery of milk a day—were largely overcome by the relatively cool weather of the summer, by unusual effort in milk inspection (including the employment of an emergency corps of inspectors, known as 'milk scouts'), and by an enormous development of the sterilized milk service fostered by the Woman's Club and Hospital Association. As a matter of record the mortality of infants and young children during 1903 was lower than ever before known—8.8% less than in 1902, 9.4% less than in 1901, and 57% less than the average of the period between the 2 census years, 1890 and 1900. In 1891 the deaths of children under 5 years of age numbered 110.38 in every 10,000 of population; in 1903 they were only 41.7."

Mortality and Morbidity in Indiana in December.—The monthly report of the Indiana State Board of Health says: Measles was reported from all parts of the State in December. There were 9 deaths, and the lowest estimate of cases is 10,000. Tonsillitis was second in prevalence, many of the cases, no doubt, being diphtheria. Pneumonia was third in prevalence, then rheumatism, bronchitis, influenza, smallpox, scarlet fever, typhoid fever, diphtheria, and diarrhea, in the order named. **Smallpox.**—Five hundred and twenty-three cases with 2 deaths, in 40 counties, was reported. In the corresponding month last year there was reported 642 cases with 17 deaths, in 40 counties. Almost half of the cases, 812 in number, were reported from Clay county. The first marked epidemic of smallpox occurred in Clay county 4 years ago, and despite many deaths and a great number of severe cases, it has been impossible to secure general vaccination. **Tuberculosis.**—The deaths in this month numbered 371, a rate of 173.9 per 100,000. In the same month a year ago, the deaths numbered 319, rate 149.5. Of the deaths 165 were males, and 206 females. Of the males, 29 were fathers, between 18 and 40, and left 58 fatherless orphans under 12 years of age. Of the females, 76 were between 18 and 40, and left 151 motherless orphans under 12 years old. How many of these will find their way into orphans' asylums, and how many of the 29 widows will now need aid from the public, cannot be told. Typhoid fever caused 65 deaths. In the same month last year 91 deaths were reported. Fifty-eight of the 92 counties reported the disease present, 701 cases in all. **Pneumonia** caused 392 deaths; rate, 183.8 per 100,000. In the same month last year, 267 deaths were reported, a rate of 125.1. The city rate was 275.1,

the country 136.5. By other causes than above, the deaths were: Diphtheria, 54; scarlet fever, 34; diarrheal diseases, 23; cerebrospinal meningitis, 34; influenza, 35; puerperal fever, 10; cancer, 91; violence, 153.

FOREIGN NEWS AND NOTES

GENERAL.

Smoke of Cigarets Harmful.—A German chemist, Dr. J. Pontag, has been analyzing the smoke of the cigaret and he finds therein a harmful amount of hydrocyanic, alias prussic acid, one of the most energetic poisons; pyridin, ammonia, nicotin, and carbonic oxid. The smoker will be interested, if not delighted, to learn that about half of the nicotin originally in the tobacco remained in the smoke, but the proportion was found to depend largely upon the length of the mouthpiece. The chemist or physician who has a good word to say for the physiologic effects of cigaret smoking has yet to be discovered, but the smoking goes on all the same.—[*London Telegraph*.]

OBITUARIES.

Needham M. Wilson, at his home in Philadelphia, January 19, after three months' illness, aged 67; a graduate of Jefferson Medical College in 1865. He was widely known in the vicinity in which he lived, where he had a secure place in the hearts of all those who knew him. He was a Mason and a member of Jefferson Medical College Alumni Association.

Edmund S. Hanna, at his home in East Orange, January 17; a graduate of Jefferson Medical College in 1850. He at one time practised in Pittsburg, and was surgeon to the Lehigh County Workhouse and Children's Church Home, the Baltimore and Ohio Railroad, and the Lehigh Valley Railroad for many years. He retired from practice in 1888.

Robert Sharp committed suicide at his home in Atglen, Pa., January 20, by shooting himself through the heart. Worry from being afflicted with Bright's disease is said to have caused the rash act. He was a graduate of Jefferson Medical College, Philadelphia, in 1881, and at the time of his death was 52 years of age.

James P. Henry, at his home in Independence, Mo., January 13, aged 85. He was a graduate from the Transylvania University, at Lexington, Ky., and began the practice of medicine in Independence in 1849. This venerable physician was widely and favorably known in the locality in which he lived.

Benjamin G. Dysart, at his home in Paris, Mo., from pneumonia, aged 70. He was a graduate of Jefferson Medical College in 1859; he was surgeon to Cockrell's Brigade of the Confederate army during the Civil war, and many stories are told of his personal bravery.

Edward B. Dana, Jr., at his home in Metuchen, N. J., January 21, of pneumonia, aged 43; a graduate of the College of Physicians and Surgeons, N. Y., in 1889. He was president of the Board of Health and of the Board of Education in his home city.

Harvey C. Fraker, at his home in Columbus, Ohio, January 9, from aneurysm of the aorta, aged 53; a graduate of the University of Wooster, Cleveland, in 1873, and professor of pathology in the Ohio Medical University.

Francis Woodley Harrell, recently, at the Waldorf-Astoria, New York, with double pneumonia, aged 44. He was a graduate of the University of Maryland, and had for a number of years resided in Mexico.

Alban Spooner, at his home in Beverly, N. J., January 18, aged 26; a graduate of Hahnemann Medical College, Philadelphia, with which institution he was connected at the time of his death.

Charles W. Bishop, was killed by a street car accident, in Chicago, January 11. His home was at Tinley Park, Ill. A graduate of the Bennett College of Eclectic Medicine and Surgery, in 1878.

J. E. Pierce, at his home in Middletown, Ind., January 9, from a gunshot wound of the head, aged 40; a graduate of the College of Physicians and Surgeons, Indianapolis, in 1895.

Virgil M. D. Marcy, at his home in Cape May, January 21, aged 81; a graduate of Yale College, in 1844 and of the University of Maryland, in 1846. He was prominent in masonic circles.

Galus A. Nash, for many years a wellknown physician in New York City, died on Saturday at his home. He was 78 years old, and had been practising in that city fifty years.

Frederick H. Stahle, of San Francisco, committed suicide by inhaling illuminating gas, January 5, aged 41; a graduate of Cooper Medical College, San Francisco, in 1888.

William H. Neville, of Philadelphia, died suddenly in a street car, January 22, aged 64. He was a graduate of the Hahnemann Medical College.

M. Marcus, at his home in Philadelphia, recently, in his 27th year; a graduate of the Medico-Chirurgical College. His death was caused by pneumonia.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

AN IMPROVED SNARE FOR THE REMOVAL OF THE FAUCIAL TONSIL.

BY

CHARLES NELSON SPRATT, B.S., M.D.,
of Minneapolis, Minn.

The removal of the faucial tonsil by means of the tonsillotome is so frequently followed by severe hemorrhage, especially in adults, that the use of this instrument involves considerable danger, and one that is too often underrated. Fatal cases are rare, it is true, but severe bleeding is frequent. The older the patient the greater is the danger. In the child the tonsil is generally soft, hemorrhage is brisk, but soon ceases. As adult life is reached, fibrous tissue is present in greater amount, the bloodvessels are larger, and their elastic walls collapse less easily. Hemorrhage is therefore frequent, profuse, and prolonged.

During my service on the house staff of the New York Eye and Ear Infirmary, over 900 operations were done for the removal of hypertrophied tonsils. Practically all of these were performed on patients under 12. In only 3 cases was there severe hemorrhage following the operation. During this period there were also 18 operations of the same nature done upon patients over 17. Among this comparatively small number, hemorrhages which were severe and alarming, at least to

loop rests in a groove in the ring and is not exposed until the slide on the handle is pulled. A pin in the instrument just back of the ring prevents the wire being pulled into the canula. This obviates the inconvenience of rewiring the instrument each time it is used. All that is necessary is to reform the loop and place in the groove. If the tissue is very fibrous, the screw wheel will bring sufficient tension on the wire to cut the toughest tonsil.

The advantage of this snare over the simple wire loop is that the tonsil is forced through the fenestrum and then cut by the wire. The loop being concealed in a groove inside the ring, is entirely out of the way until the tonsil is well engaged. I have used the slide on the handle on account of its simplicity. If desired, however, the more complicated and expensive Farlow handle can be used, the ring with the hidden wire loop being the important feature of the instrument.

In concluding, I wish to emphasize the following points:

1. The tonsillotome is not a safe instrument to use on adults.
2. The instrument described is just as convenient and simple in action as the tonsillotome, but is without its dangers.
3. As the tonsil is forced through the fenestrum by the pressure of the ring on the tissue about the gland, the use of the vulsellum forceps is unnecessary, and the operation may be done by the sense of touch.
4. The instrument does not require rewiring during the operation.

NOTE.—The illustration of the snare shows the screw wheel entirely too large. For this reason the instrument has a clumsy appearance. A properly made instrument is manufactured by Codman & Shurtleff, Boston.

CONCERNING PRODUCTION OF ANTITOXIN.

To the Editor of American Medicine:—Your editorial of January 23, in which you suggest "the appointment of a committee of experts, medical men and pathologists, whose names alone would be a guarantee of confidence in their report, and who should at once investigate the facts and end a doubt which is harmful alike to the manufacturer, the physician, and the community," on the question of a trust having been formed to raise the prices of antitoxin, is to the point.

Serum therapy proves one fact, that it is impossible to completely neutralize a toxin by an antitoxin, for free portions of both substances are always present in any mixture that may be made. It is therefore necessary that a surplus of the antitoxic substance be present to render the toxic substance inert. This means that large doses of antitoxin are necessary. Authorities are agreed upon the fact that whatever irritation may occur to the body of the patient is caused entirely by the serum; consequently, large doses of concentrated antitoxin are required to secure the best results.

We have been preparing antitoxin especially to meet the demand of American physicians for the past 9 years. At first there were 3 grades of antitoxin offered, known as "Standard," containing 100 units per cc.; "Potent," containing 250 units per cc.; "Extra Potent," containing 500 units per cc. The demand being principally for the 2 latter strengths, we, some years ago, cut out the weaker strength entirely, and placed but 2 potencies of serum on the market, known as Standard, containing 250 units per cc.; Concentrated, containing 500 units per cc.

The demand for the higher potency serum has largely increased during the past 2 years, while the demand for the weaker serum has materially diminished; consequently, on January 1 we decided to discontinue offering the lower potency serum, and offered but one strength, corresponding to the higher potency.

We had not supplied the Chicago Board of Health, nor would we, since the price at which they were purchasing their supply was less than what it could be made for; and as we discontinued offering the weaker product, when we were asked for quotation by the Chicago Board of Health, we quoted the high potency serum only. Had we been requested by the Secretary of the Chicago Board of Health to furnish a lower potency serum, we should have been pleased to quote a price at about cost of production.

In determining to offer but one potency of antitoxin we felt

Fig. 1.—Tonsil snare.

the patient and his friends, followed in 6 cases. By a severe hemorrhage is meant a loss of 500 cc. or more of blood. In 2 cases each patient lost more than a liter by actual measurement. Two other patients, while not losing so much, showed signs of collapse. In children, after the combined adenoid and tonsil operation, a loss of 150 cc. of blood is unusual. The average amount is between 90 cc. and 120 cc. These facts convince me that the tonsillotome ought never to be employed in operating on adults. The cold wire snare is safer, and ought to be the instrument used, as the removal of a hypertrophied tonsil is then followed only by moderate oozing.

When the patient is not under a general anesthetic, the simple wire loop is quite satisfactory. If the patient is anesthetized, and is on his back, the instrument shown in the accompanying illustration (Fig. 1.) has proved more satisfactory, as no vulsellum forceps are required, and the operation can be done by the sense of touch, just as when a McKenzie

Fig. 2.—Tonsil separator.

tonsillotome is used. The instrument is similar to the tonsillotome, the sharp blade being replaced by a wire loop. Like all other snares, this is not suitable for the removal of the flat, submerged tonsil. In such conditions the punch forceps are to be used.

The tonsil is first well separated from the pillars by any suitable instrument. I use the one shown in Figure 2. This resembles an Asch separator with a longer shank and a larger handle. The patient's jaws are well opened and strong pressure is made by the assistant beneath the angle of the patient's jaw. The ring with the oval fenestrum is firmly pressed against the tonsil. The gland is thus forced through the opening, and the wire is drawn tight until the base is cut through. The wire

that the poor were entitled to receive the same advantage of concentrated serum as the well-to-do. We have, however, always endeavored to meet every reasonable demand that has been made for legitimate preparations, and if the Board of Health of Chicago, or any other city or State, request a low potency serum, we shall be glad to furnish it, and at about cost.

Meanwhile, if the city of Chicago, or any other city having a regularly organized health department, refuses to supply reputable physicians with antitoxin for the treatment of the needy poor, we shall be glad to donate sufficient antitoxin to meet such emergencies. The conscientious manufacturer recognizes the importance of saving life from diphtheria, and protecting those exposed to contagion by immunization, just as thoroughly as can the conscientious physician.

Every package of antitoxin is dated, and we exchange for a fresh supply any serum not used within the time specified on label.

Our experience having proved that American physicians demand the more concentrated product, since at least two-thirds of all the lower potency distributed was returned to us for exchange; and since this exchange added a very large expense to the cost of antitoxin, we believed that by having but one strength of serum, and that the higher potency, we would meet the demand of physicians and that returns would be largely controlled, and in this way we could save the expense of exchange and thus warrant the reduction in price. This is exactly what has been done. We are now offering but one grade of antitoxin, practically corresponding in strength to the former concentrated serum, and have reduced our prices as follows:

	Present Price	Former Price
500 units	\$1.10	\$1.25
1,000 units	2.00	2.25
2,000 units	3.50	4.00
3,000 units	5.00	5.75
4,000 units	6.50	7.50

or an average reduction of 15%.

The firms engaged in producing antitoxin have invested millions of dollars, and are safeguarding the production of the serum by every means that science, skill and money can command. Furthermore, we recognize that it is only by producing the highest standard of quality that such a business can be successfully continued.

The expense of preparing antitoxin during the past few years has increased enormously. To this expense must be added the cost of syringes, needles and the various devices for injecting the serum direct to the patient. In spite of this extra expense, however, we believe that the cost of distribution will be so materially decreased by reducing the returns for exchange of the lower potency serum, that the reduction in prices noted above, can be made.

We do not consider it practicable or desirable for city or State Health Departments, as at present constituted, to furnish antitoxin, because such departments are continually changing, through political influence. The experience of Naples, and the more recent one of St. Louis, show what may occur in municipal laboratories, where appointments are made irrespective of ability.

To the best of our knowledge, not a single accident can be traced to the products of private laboratories, where the directors and assistants are chosen solely by their scientific attainments and sterling integrity, and not through any political or outside influence. It never enters the manufacturer's mind to consider whether an employe is affiliated with either of the leading political parties, or if he has any political influence.

There is no trust existing among the manufacturers of antitoxin, nor do we believe such an organization is possible, since the preparation of antitoxin is only a portion of the general business of each firm.

The United States Government has strict regulations safeguarding the production of serum, and furthermore, the products are purchased, from time to time, in the open market and subjected to tests, and it would be little short of folly for any firm to attempt to place an inferior product on the market.

Relative to the profits accruing from the production of antitoxin, we shall be gratified to have any committee of

experts examine our books and ascertain the exact profits earned in the production of antitoxin.

As purveyors to the medical profession, we should consider that we were but poorly repaying the confidence which the American physicians have shown in our products, by not protecting and safeguarding their very best interests, and we hold that all efforts made to raise the standard or quality of a preparation such as diphtheria antitoxin, are to be regarded as a benefit to the physician and the general public.

H. K. MULFORD COMPANY,
H. K. MULFORD.

A CASE OF MULTIPLE ADENOMA OF THE PROSTATE, COMPLICATED BY VESICAL CALCULUS. PERINEAL PROSTATECTOMY.

BY

G. FRANK LYDSTON, M.D.,
of Chicago.

Professor of Genitourinary Surgery and Syphilology, State University of Illinois; Attending Surgeon, St. Mary's and Samaritan Hospitals, etc.

J. L., aged 59, a retired merchant, was referred to me by Dr. C. H. Stimson, of Newark, Ohio. Aside from his urinary disturbance, the patient had always been a very healthy and active man. For a period of more than 10 years he had been troubled with frequent micturition. For several years past urination had been very frequent and painful; the urine had been loaded with pus. There had been from time to time slight hematuria. For some time past there had been a gradual loss of flesh, the patient being some 20 pounds under normal weight. Examination showed a very marked, uniform enlargement of the prostate, with a large median tumor. There was 3 ounces of purulent residual urine which, aside from the pus, was normal. Careful examination failed to detect stone. No cystoscopic examination was made, as instrumentation was extremely difficult and painful, being also attended by hemorrhage. A further consideration was the fact that a long cystoscopic examination would only complicate matters, as operation was to be performed anyway.

Operation.—After 5 days' preparatory treatment, perineal prostatectomy was performed. A Y-shaped incision was made and my prostatic tractor employed. By the use of this instrument there was, as is usual, no difficulty whatever in bringing the prostate well down into the perineal wound. The operation was somewhat prolonged because of the number of tumors, although there was very little difficulty in shelling them out with the finger. The lateral lobes contained 15 distinct adenomas of varying size. After their removal, a large sessile median tumor was delivered by a volsellum, and freed from its attachments by the finger with great ease. Beneath the median growth, completely concealed by it, and occupying a concavity on its interior surface, was a good-sized calculus. This rolled out on to the floor of the bladder as soon as the median "lobe" was delivered, and was readily removed with the forceps. Including the median lobe there were 15 separate and distinct adenomatous tumors in all. The hemorrhage during the operation was very slight, as is usually the case when it is practicable to enucleate entirely with the finger. The bladder was drained by a large perineal tube, which was removed on the fifth day. On the eighth day following the operation, micturition occurred *per vias naturales* and on the fourteenth day the patient left the hospital and reported at my office, having almost complete control of the vesical sphincter, and micturition being normal in frequency.

RÖTHELN—UNPUBLISHED SYMPTOMS.

BY

J. D. MADDOX, M.D.,
of Rockport, Ohio.

To the Editor of American Medicine.—In an epidemic of röteln or German measles now under observation I notice two symptoms constant in every case so far, that I have failed to find mentioned by any author I have consulted; viz., a bloody discharge from the nose as if produced by rupture of the engorged capillaries; and soreness, stiffness and swelling of the fingers, soreness and sometimes stiffness of the wrists, elbows and knees, and less frequently of the ankles, as if there was present transient inflammation of the synovial membranes. In some cases also there seems to be the same condition present in the sheaths of some of the tendons. Have these been referred to by any writer?

ORIGINAL ARTICLES

THE DIAGNOSIS AND TREATMENT OF GALLSTONES.¹

BY

MAX J. STERN, M.D.,

of Philadelphia.

I spent the last spring and part of the summer with Professor Hans Kehr, in Halberstadt, Germany, at his private clinic and received my special training in the diagnosis and treatment of gallstones from him. I have imbibed his views, and in presenting this paper it must be understood that the vast majority of the opinions I present are those he has either communicated to me in person or has given me the privilege of freely drawing upon from his numerous writings.

There is an absolute essential to the correct understanding of the etiology of gallstones, and that is a thorough knowledge of the pathologic anatomy of the disease. No one can successfully—it would be better if I said intelligibly—treat a case of gallstones, certainly not operatively, unless such knowledge has been previously acquired. It is obvious, where this has been obtained on the living subject, it is of infinitely greater value than when acquired on the postmortem table or in the dissecting-room. When one considers that a keen observer like Kehr has operated in nearly 800 cases of gallstones it is not to be wondered at that he should have attained a remarkable proficiency in the diagnosis and treatment of this affection. I look upon myself as extremely fortunate in having been able to obtain my training from so ripe a teacher. While my experience in this affection has been infinitesimal as compared to his, yet it must be borne in mind that I had the advantage of his riper judgment and had the benefit of receiving maxims that he had to correlate from a vast experience.

Diagnosis.—Gallstones are probably one of the most common affections to which human flesh is heir. Kehr believes that one in every ten adults is the subject of gallstones. But it must be borne in mind that gallstones in themselves do not produce the phenomena with which we are familiar and which we associate with the diseases that are found in combination with these concretions. Riedel says that only about 5% of those affected ever have cause to consult a physician because of their presence. There is, then, another element which must exist in addition to the gallstones to produce the phenomena of gallstone disease. This element is inflammation, and inflammation is infection, hence gallstones plus infection are the essential features of gallstone disease. For want of a better term, the name latent has been applied to a collection of gallstones in the biliary passages which are not or have not been associated with acute or chronic inflammatory processes. Subjects afflicted with this condition may pass through life without ever experiencing any inconvenience from the concretions. We have then to deal with the 5% which become infected. It is now scarcely needless to say that when the term cholelithiasis is used by me it must be understood to apply only to cases in which there is infection with the concretions; the other cases are of absolutely no concern to either physician or surgeon. That this view has not yet received general acceptance can best be illustrated by a remark made to me recently by one of our eminent surgical associates. He stated that "if he knew his gallbladder contained calculi, colics or no colics, he would have them out at once." I sincerely hope for the good of humanity that this view will never prevail.

The first expression of cholelithiasis is pain—and this is the announcement of an acute infective process in the gallbladder. Pain is what we are summoned to allay and is undoubtedly in the vast majority of cases the most prominent symptom of gallstone disease. The

pain is infinitely variable, and may differ from a slight discomfort, a sensation of pressure in the epigastrium or the region of the gallbladder, a moderate cramp of the stomach, to the terrific colics which prostrate women who have stoically passed through the agonies of childbirth. While pressure will scarcely get a response from an acute serous cholecystitis, which may pass off in a few hours, the gentlest touch of the most skilful surgeon can not be borne without infinite agony over an acute purulent inflammation of the gallbladder. If a stone be lodged in the cystic duct, then there is superadded the pain of obstruction. This is probably more painful than when the stone passes the papilla of the duodenum. When the stones are confined to the gallbladder the pain is primarily restricted to the right hypochondrium. The pain may radiate to the breast and back, and this is more particularly true as the stones find an exit from the gallbladder. If they are lodged in the common duct we have pain upon pressure in the epigastrium and the left hypochondrium. The most common error is to confound this condition with cholera morbus. The pain of cholelithiasis is exquisitely cramp-like, but may, too, be boring, burning, nagging, and fixed in a well-defined place. It is generally on the right side and localized in the region of the gallbladder, whence it frequently radiates to the back, to the right shoulder-blade, and to the breast. It may be confined to a circumscribed area under the right rectus abdominis without assuming any radiation. It may also appear as a cramp in the stomach, but gentle palpation in the epigastrium will show that the middle line is free from pain, and that the sensitive area is confined to the locality of the gallbladder.

The pains in cholelithiasis always appear suddenly, and generally irrespective of the diet one has indulged in; one may with impunity have ingested the heaviest diet, drank champagne, whisky, or beer, to be suddenly attacked during a period of the most restricted diet. In gallstone disease the stomach contents will usually show either normal or deficient hydrochloric acid, unless there be a condition present not dependent on the cholelithiasis. The usual concomitants of gallstones are either adhesions or pyloric stenosis. The vast majority of those suffering from gallstones are the subjects of troublesome stomachic derangements; these are not dependent upon a primary gastric disturbance, but are due to peripyloritis, which is the common concomitant of cholecystitis. I believe it would be safe to say that the vast majority of the pains which are called cramps and cholera morbus are really gallstone colics. With a more diffuse knowledge of the disease and a requisite training in diagnosis, we shall hear less of these affections. All pains which are felt in the lower portion of the abdomen excite suspicion toward the appendix, so should all pains in the epigastrium and the right hypochondrium lead the physician to a most careful examination of the gallbladder. In no case of cramps or cholera morbus or gastric neuralgia or kindred affections should the physician fail to palpate carefully the lower border of the liver. Sensitiveness to pressure over the region of the gallbladder should at once be sufficient to differentiate and lead one to believe that they are dealing with gallstones. I recently saw a patient with gallstone colic who had been treated by the attendant for intercostal neuralgia. Kehr informed me that he once had a patient with lead colic sent to him to be operated upon for gallstones. Similar mistakes may occur oftener than one should be led to believe; the differentiation between ulcer ventriculi and gallstones is more difficult, yet even here it is generally possible to come to a clear understanding of the case, unless it should happen as it sometimes does that ulcer ventriculi and cholelithiasis occur synchronously. When the infiltrated ulcer is accessible to palpation, as occurs when the ulcer occupies the anterior wall of the lesser curvature of the stomach, the demonstration of the ulcer should occasion no great difficulty. The pain of

¹ Read before the Northern Medical Society of Philadelphia.

ulcer is more particularly dependent upon the quantity and quality of the food ingested, and begins either immediately or very shortly after eating. It rarely occurs when the stomach is empty, while the most usual time for gallstone colic is either during the night or at some other time, generally some hours after eating. In differentiating between appendicitis and cholelithiasis great difficulty may be met if the appendix is turned upward, so that its extremity may reach to the lower liver border. In such cases, certainly in the acute form, the points given for differentiation are more fanciful than real. The patients vomit in either instance, the pain is alike, flatus ceases to pass, the bowels are constipated, the fever in either may be moderate or high and both give a tumor in the same region. There are probably minute points in differentiation which lead the trained surgeon to arrive at a correct diagnosis, yet it is doubtful if they could be enumerated sufficiently clearly to aid the general practitioner to arrive at a correct conclusion. In such instances it is fortunate that both conditions require the same treatment. It would be entirely beyond the limits of this paper to differentiate between gallstones and all the diseases with which they may be confounded, yet there is one more I must mention, that between cholelithiasis and right-sided floating kidney. According to Kehr the most important point in the differential diagnosis is the characteristic sensation which one experiences with the reposition of a floating kidney; the kidney suddenly darts upward and backward with a flop, like when one reduces a hernia, often to remain in its new position. The gallbladder, if it be not bound down by adhesions, may also be pushed upward and backward; yet the moment that pressure be released it will return to its original position, immediately behind the anterior abdominal wall. In the case of the floating kidney, if it be replaced and the patient be quiescent in bed, it will usually retain its new position throughout quiescence. The gallbladder always returns to the anterior abdominal wall. The gallbladder may be moved laterally, but has a fixed pendulous point at the lower liver margin. The kidney, too, may be moved laterally, but has no fixation point at the liver border. Fortunately lithiasis pancreatica is an extremely rare affection, for the passage of a pancreatic stone into the intestine will naturally occasion the same train of symptoms as those aroused by a gallstone passing the papillæ of the duodenum; these affections cannot be differentiated. No error in diagnosis should ever occur in cholelithiasis when a tumor exists in the right hypochondrium whose form and movement are inherent to a distended gallbladder. In women who have borne children and thin individuals the distended bladder lies so closely to the abdominal wall that one cannot only recognize its dome-like prominence, but follow its movements as it rises and falls with the liver in the respiratory participation of the diaphragm. In the obese and occasionally in athletes with very rigid abdominal walls the determination of the site of the gallbladder is often impossible, yet I have seen the gallbladder beautifully outlined in a case of hydrops in a woman weighing nearly 300 pounds. The less often the bladder has been the seat of a pre-existing inflammation, the more distensible will be its walls. A bladder which has been the seat of frequent inflammations has had the elasticity of its walls so diminished that the severest acute purulent cholecystitis may occasion only a slight tumor. The size of the tumor, therefore, can give no indication of the gravity of the affection. The locality of the gallbladder must always be sought at the liver margin; it can only be found at the ninth or tenth rib, when the liver occupies the normal position. If the liver be greatly enlarged it goes without saying that the gallbladder must be sought for lower in the abdomen, indeed in deeply dependent livers it may be sought for as low as Poupart's ligament. Liver enlargements rarely occur in

acute cholecystitis. The swollen liver is usually an accompaniment of a cholangitis. At times the gallbladder does not occupy its normal site with reference to its usual position at the liver margin. It may be more internal or external than usually sought for, or it may lie very deep in the liver bed. Again I recall seeing a case in Professor Kehr's clinic, in which the bladder was sought for in its usual site and not found. A week later the gallbladder was found on the left side at the eighth or ninth rib. The shapes of gallbladders vary greatly, even those not the subject of inflammatory process. They may be more or less irregularly spheric, or ovoid or elongated like a pickle, and vary in size from a cherry to an apple. It should always be borne in mind that one may be suffering from a severe acute empyema of the gallbladder and yet it may be impossible to demonstrate a tumor of the infected organ. There is just one other source of error to which attention might here be called. Tumors of the gallbladder need not necessarily participate in the respiratory movements. It sometimes happens that the bladder is so firmly bound down by adhesions that its movements are extremely limited—and if in addition to this the pain be very severe the breathing on the affected side is very shallow and we have practically an immobile tumor.

We now come to jaundice, a symptom which curiously enough is associated in the minds of many practitioners as the most important point in the diagnosis of cholelithiasis, and yet occurs least frequently. It is absent in the vast majority of cases and probably occurs in not more than, if as many as, 10% of all cases of cholelithiasis. I have been taught to believe that jaundice is not an expression only, of a damming up of bile by an obstruction below the orifice of the hepatic duct, but that it is probably a disease of the individual liver cell, communicated by an extension of an inflammatory invasion from the biliary passages or some affection of the liver *per se* in which no obstruction to the flow of bile exists in the biliary ducts. Kehr is fond of citing a case of obstruction in the common duct in which he removed a calculus and drained the hepatic duct. In spite of the passage through the tube of enormous quantities of bile the icterus constantly became more intense until the day of the patient's death, some time subsequently. Then again, *per contra*, cases are occasionally met in which a stone the size of a walnut has been recovered from the common duct, and which seemed to occlude it absolutely, and yet the patient had had but a fleeting jaundice or none at all. Therefore too much reliance must not be placed upon jaundice, its presence not only frequently does not help to clear up a doubtful case, but indeed often adds materially to the difficulty of arriving at a satisfactory diagnosis.

Colics dependent upon the presence of an acute obstruction by a calculus in the common duct are those familiarly known to almost every practitioner. The patient is suddenly, without any premonition, seized with a violent colic. The pain is usually most intense in the right hypochondrium, radiating toward the back and shoulder, toward the stomach, and toward the breast. It may be so severe that those inured to pain give vent to the most heartrending cries, and piteously beg of their attendants for relief from the intolerable suffering. The colic is due to the passage of the stone through the tortuous cystic duct, the common duct and then on through the papilla into the duodenum. With the entrance of the stone into the intestine spontaneous relief occurs. During this stage we may have fever, usually, however, not of a very high grade, nausea, vomiting, hepatic enlargement, and jaundice. The jaundice in these acute cases sometimes, not always, appears after the stone has passed through the common duct. Sometimes the onset of the colic in cases of acute obstruction of the common duct, particularly in those who have been the subjects of frequent attacks, is not so sudden as described above, but there may be exhibited

premonitory pains generally referred to the stomach which warn the patient of an approaching attack.

There is another point of great importance in connection with diagnosis in cholelithiasis. It is this: The results of cholelithiac inflammations, patients from whom the stones have passed, have resulting conditions which so closely resemble true gallstone colics that it is impossible to differentiate them. These are generally either adhesions with neighboring organs, bands of adhesions crossing the ducts, kinks or stenoses, due to preexisting inflammations within the tubes or bladder.

For arriving at a diagnosis in cholelithiasis too much attention cannot be given to the history and no point is too unimportant or too minute to be omitted. It must always be borne in mind that the history of the case is the most, I state this unequivocally, the most important factor in arriving at a correct solution of the case. Bear in mind, too, that jaundice is so rarely associated with inflammatory processes of the gallbladder that it would almost be safe to say that it never occurs. It is very rare, too, at the onset of any gallstone disease. A true gallstone colic may have taken place and recovery have been effected, and no stone subsequently recovered by the most careful sieving of the feces. The stone in such cases has not passed through the common duct, but been returned from the cystic duct to the bladder.

It frequently happens that cholelithiasis is complicated by affections in neighboring organs. Particularly is this true of the stomach and pancreas. In a recent communication sent me by Kehr he stated that he found the head of the pancreas affected in 66% of the patients operated upon by him during the last year. The most horrible complications that the surgeon meets are diffuse cholangitis, sepsis and perforation peritonitis. It should be borne in mind by the physician that these are always the results of delay, and might have been avoided by early operation. The unfortunate factor is that the patient almost invariably succumbs to the disease.

The various forms of cholelithiasis so frequently fuse from one to the other that a sharp line of demarcation cannot always be drawn between them. We may be dealing today with a condition of acute cholecystitis which tomorrow will develop into an acute obstruction of the choledochus and in two months have become a chronic common duct obstruction. A recurrent cholecystitis which has existed for years may develop suddenly into an acute sterile and completely latent hydrops of the bladder. A chronic obstruction of the common duct may at any time have added to it an empyema of the gallbladder. In an acute obstruction of the common duct we may suddenly have a perforation of an empyemic gallbladder. Cases of cholelithiasis will at times present themselves which are impossible to classify under a specific head; while one of several forms or a combination of them may be surmised, a positive conclusion can at times only be reached after the abdominal incision has been made.

From the foregoing, conclusions can be drawn that any schematic presentation of the various forms of cholelithiasis must be accepted with reservations. Hard and fast drawn lines are not always present, therefore the following must be accepted as only embodying the more salient points of the various types of gallstone affections. I will name the diffuse variations in which the disease is generally found, its more prominent symptoms, the diagnosis, and the line of treatment for its relief.

I.

(a) *Variety of Disease.*—Stones in the gallbladder, the movements of which affect but slightly or not at all their relative positions. The cysticus is patulous. The bile is clear, free of virulent bacteria, and there are no adhesions.

(b) *Symptoms.*—Symptoms are almost constantly absent (latent state). Occasionally epigastric pain, due to a transient obstruction of an otherwise patulous cystic duct. Jaundice is absent, no passage of stones. No swelling of the liver.

(c) *Diagnosis.*—Results of palpation are negative, at most a

slight sensitiveness to pressure, by bimanual examination, in the region of the gallbladder. This condition may frequently be confounded with ulcer rotundum, intestinal colic, floating kidney and hernia of the linea alba.

(d) *Treatment.*—Medical treatment is sufficient; a course of treatment of the kind and in the manner of that employed at Carlsbad, to establish permanently if possible the period of latency of the cholelithiasis.

II.

(a) *Variety of Disease.*—Acute cholelithiasis in a relatively healthy gallbladder. A large stone usually occupies the neck of the gallbladder. The fluid exudate is found in a condition between cloudy (?) and purulent (?). The walls are thickened.

(b) *Symptoms.*—Tumor of the gallbladder or a prominent Riedel's lobe. Rarely jaundice. Severe pain in the region of the stomach. Marked tension and resistance of the upper portions of the abdomen. Great sensitiveness to pressure. The general condition in mild infection is but little altered, in severe infection markedly changed. (Cholelithiasis acutissima event with cholangitis.) Peritonitis circumscripta (pericholecystitis). Elevation of temperature may be present or absent. Liver is only enlarged in the event of a coexisting cholangitis. Usually no passage of a stone. When the cholecystitis terminates with the passage of a stone there is produced an acute obstruction of the common duct.

(c) *Diagnosis.*—The diagnosis is easy. It may be confounded with appendicitis, particularly if the vermiform appendix is turned upward and lies in the neighborhood of the liver. The diagnosis must establish that the tumor felt is one of the gallbladder, and that through its form, mobility, tension, etc.

(d) *Treatment.*—The best treatment is operative. By the administration of drugs, chiefly purgative and particularly salines, the inflammation may be allayed, but the stone remains as a constant menace. In cholecystitis, cystostomy, the establishment of a fistula is the proper procedure. (Normal-verfahren.)

III.

(a) *Variety of Disease.*—Stones in a gallbladder which has already been the seat of an inflammatory process. Cysticus at present patulous. Adhesions exist between the gallbladder and intestines and mesentery.

(b) *Symptoms.*—Objective symptoms almost entirely absent. No jaundice. No passage of stones, and no enlargement of the liver. At times violent colics brought about by strangulation of the cysticus after an overdistention of the gallbladder. There may be frequent vomiting and intense pressure pain. In the intervals there may be complete rest with an entire absence of all symptoms—a latent state.

(c) *Diagnosis.*—In the interval palpation is negative; there may be slight pain on pressure in the gallbladder region. During the attack a tumor of the gallbladder will only be demonstrable if the walls of the bladder are still sufficiently elastic to be capable of distention by the exudate.

(d) *Treatment.*—Operation is imperatively demanded in these frequently recurring and painful cases. The best procedure is cystectomy combined, if possible, with drainage of the hepatic duct. The Carlsbad cure in these cases has but a fleeting effect.

IV.

(a) *Variety of Disease.*—Acute cholecystitis in a previously atrophied bladder, having frequently been the seat of inflammation; this variety belongs to the chronic recurrent form of cholecystitis. Cysticus obliterated or obstructed by stones. Numerous enveloping (?) adhesions. Exudate small, and may range from mucus to purulent. Fistula between the gallbladder and intestines.

(b) *Symptoms.*—A tumor of the gallbladder is not palpable, because the bladder lies high and under the border of the liver. Severe pains, often in the stomach, and not unlike those found in acute cholecystitis in a relatively healthy gallbladder. There is a frequent change in the appearance of the symptoms. Jaundice is very rare, and if it exists, a stone is traveling from the cysticus into the common duct.

(c) *Diagnosis.*—The diagnosis is difficult because of the negative palpation. A most careful study of the anamnesis is the very best aid to a diagnosis. In cases of severe general infection, purulent cholecystitis without demonstrable tumor and no very pronounced colics, has been confounded with typhoid and malarial fever and sepsis.

(d) *Treatment.*—The best is operation—ectomy—as the Carlsbad cure is pretty generally ineffective. The best time is during the interval between attacks. (Schlauchverfahren sind möglichst einzuschränken.)

V.

(a) *Variety of Disease.*—An empty gallbladder which has previously been the seat of inflammation and when adhesions exist between the gallbladder and intestines.

(b) *Symptoms.*—Occasional cramps. Sometimes violent colics. There may be vomiting, which may be severe, and pressure pain. Frequent change of posture; rising from a recumbent posture will produce pain. Generally in the interval between the acute attacks there is a complete latent state.

(c) *Diagnosis*.—Palpation is generally negative. There may be slight pain in the region of the gallbladder. The patient, however, throughout suffers very much. The adhesions may lead to stenosis of the pylorus, ileus, or a constant feeling of pressure about the stomach.

(d) *Treatment*.—When suffering persists, or frequently recurs, operation is imperatively demanded. The best procedure is ectomy, and if peripyloritis coexist a gastroenterostomy. Pyloroplasty is said not to be so certain in its effects, but I have seen some admirable results after it.

VI.

(a) *Variety of Disease*.—Hydrops of the gallbladder. Cystic duct obstructed by stones, or entirely obliterated. The fluid in the bladder is clear, and if infected, as I believe it always is, the type is mild. The walls are exceedingly thin.

(b) *Symptoms*.—Symptoms may be absent, excepting that the patient's attention is drawn to the anomalous condition of a tumor existing in the abdomen. There may be frequent cramps, stomachache. No passage of gallstones, no icterus, no enlargement of the liver. At times there may be present Riedel's flap—i. e., the tongue-like projection of the liver. It is doubtful if the contents are ever sterile, although the infection is generally of a mild type. This may, however, and at times does develop into a graver form, i. e., the more severe type of infection.

(c) *Diagnosis*.—The diagnosis is easy; one must only guard against the possibility of confounding this condition with a floating kidney. If not bound down by adhesions the tumor is readily movable, particularly laterally, and may be pressed into the abdominal depth, but immediately assumes its former position. There is little sensitiveness to pressure. Hydrops in a shrunken gallbladder does not produce a palpable tumor, and in consequence, as in acute cholecystitis in a previously atrophied bladder which has been the seat of frequent inflammations, the diagnosis is difficult.

(d) *Treatment*.—The treatment is operative—a cystostomy with cysticectomy, and best of all, a cystectomy.

VII.

(a) *Variety of Disease*.—Empyema of the gallbladder; pus in the gallbladder; a stone in the cystic duct; adhesions. The disease is either (1) a transition of an acute serous cholecystitis or (2) it immediately appears as an acute empyema.

(b) *Symptoms*.—At the onset we find a tumor of the gallbladder or a prominent Riedel's lobe; rarely jaundice; severe pain in the region of the stomach; marked tension and resistance in the upper portions of the abdomen; great sensitiveness to pressure; the patient's general condition markedly changed; elevation of temperature; at times chills. Liver is enlarged in the event of a coexisting cholangitis. Later in the disease, fever may be absent and the condition then closely simulates hydrops. The tumor is, however, usually smaller than in hydrops. There is no passage of a stone. The pain is restricted more particularly to the region of the gallbladder and the epigastrium and does not radiate toward the back, breast, and pelvis in nearly the same degree as in the other affections.

(c) *Diagnosis*.—Exploratory puncture is absolutely indicated. The diagnosis is similar to that of hydrops plus the virulent infection. With the participation of the peritoneum the symptoms of an infective peritonitis will preponderate. Should the gallbladder perforate we will have all the symptoms of a perforative peritonitis. At the beginning the tumor of the empyematosus gallbladder is exquisitely painful; later on, however, these pains may subside, or indeed, quite disappear. Beside the empyema of the gallbladder we may find encapsulated areas of pus in the abdominal cavity.

(d) *Treatment*.—The treatment is similar to that employed for hydrops of the bladder.

VIII.

(a) *Variety of Disease*.—Carcinoma of the gallbladder in conjunction with gallstones.

(b) *Symptoms*.—At the onset of the disease we only have digestive disturbances and no jaundice. With the invasion of the disease into the choledochus and the glands of the portal plexus we have the appearance of jaundice and ascites. The tumor is remarkably hard and uneven. Later on cachexia.

(c) *Diagnosis*.—The diagnosis in the early stages of the disease is very difficult and can usually not be established before the advent of the jaundice. Pain is absent or insignificant. With the involvement of the portal glands and the appearance of ascites the diagnosis becomes easy. A cancerous gallbladder containing stones frequently becomes the seat of an acute inflammation—empyema.

(d) *Treatment*.—In the early stages only is success to be hoped for. Then cholecystectomy with resection of the liver should be practised. With a superimposed empyema cystostomy will give amelioration.

IX.

(a) *Variety of Disease*.—Acute obstruction of the common duct by a stone.

(b) *Symptoms*.—Colic, nausea, vomiting, fever, chills, marked jaundice. Disappearance of the acute symptoms when the stone passes into the duodenum or is returned to the cystic duct. In the first of these instances the stone will generally be

passed in the feces, though often not until weeks afterward, and indeed sometimes not at all.

(c) *Diagnosis*.—The diagnosis is easy, and is the typical classic gallstone colic. The pains radiate toward the back and breast, while in cases of stones in the gallbladder, cholecystitis, the pain is more particularly confined to the gallbladder and stomach.

(d) *Treatment*.—The treatment is medical. Absolute rest; hypodermic injections of morphia, 0.2 gram to 0.3 gram (½ to ½ grain). Hot applications to the region of the gallbladder and stomach and salines. Operation is rarely necessary. If so, drainage of the hepatic duct after removal of the stone from the common duct.

X.

(a) *Variety of Disease*.—Chronic occlusion of the common duct by a stone. The stone is imbedded in the supraduodenal portion of the duct.

(b) *Symptoms*.—Moderate amount of jaundice, or there may be none, or it may be intermittent. Feces at times brown, then again clay or putty-colored. Often intermittent fever. There is generally some pain, but there may be an entire absence. The patient finally develops a cachexia. There is a hemorrhagic diathesis.

(c) *Diagnosis*.—The gallbladder generally cannot be palpated. The liver is more or less enlarged. Pain upon pressure is generally more toward the middle line. The spleen is often enlarged.

(d) *Treatment*.—Choledochotomy, cholecystectomy, and drainage of the hepatic duct.

XI.

(a) *Variety of Disease*.—Chronic occlusion of the common duct by a stone. The stone lodged in the papilla of the duodenum.

(b) *Symptoms*.—The symptoms are analogous to those when a stone is imbedded in the supraduodenal portion of the duct, with this exception, the jaundice is usually intense and changes very rarely.

(c) *Diagnosis*.—The diagnosis is also similar to that when a stone lies higher up in the duct. The gallbladder is small and atrophied when preexisting inflammation in it prevents its dilation. Otherwise we may find a tumor of the bladder.

(d) *Treatment*.—If after a reasonable time, say three months, the stone shall have become dislodged by the aid of medical means an operation becomes imperative—choledochoduodenostomy interna; probably to cholecystectomy and hepatic drainage.

XII.

(a) *Variety of Disease*.—Chronic occlusion of the common duct, by tumor or hypertrophy of the pancreas, tumor of the duodenum, or obliteration or stenosis of the common duct.

(b) *Symptoms*.—Deep jaundice, never variable, but becoming progressively more intense. Bowels always ashy gray or putty-colored. Generally an absence of fever. Pain insignificant or absent. If present rather an ache and very rarely like a colic.

(c) *Diagnosis*.—The gallbladder is generally large. The spleen is normal. The liver is enlarged. Pain upon pressure is absent or insignificant.

(d) *Treatment*.—The treatment at first, of course, must be expectant. If the obstruction is due to an interstitial pancreatitis a fistulous communication between the gallbladder and stomach offers the most brilliant results. This will probably also be true of a stenosis of the duct. Tumors of the duodenum promise less glowing results and are fraught with greater danger of a subsequent cholangitis.

A persistent latent stage is of course the best cure.

Two methods of procedure: (1) To produce stage of quiescence and latency, and (2) operation.

No solvent is known, and no remedy which will drive stones from the bladder.

An enormous number of patients who lose their pains in Carlsbad I believe would do the same in Philadelphia or elsewhere if the same attention was given to cure.

It is unquestionable that by faithful use of hot laxative springs the circulation in the liver, portal system in general, and the entire abdomen is improved. Particularly is this true when those who have been leading luxurious and sedentary or indolent lives can be made to indulge in reasonable exercise. In Carlsbad it is carried to the point of absolute fatigue. It stands to reason that, in consequence of this, catarrhal conditions of the stomach and intestines, inflammatory processes which extend from the duodenum to the common duct and from thence to the bladder should be promptly relieved. Riedel states that 95% of all gallstone diseases pass into a latent state. The other 5% are those that concern the surgeon—those cases in which life is made miserable by constant pains,

or when one is almost incapacitated by frequently recurring attacks of colic, or those cases that present conditions the existence of which are a menace to life. Operation in cholelithiasis must not be looked upon as the ultimum refugium. Neither must it be supposed that so soon as a case of gallstone disease has been diagnosed the patient should be operated upon.

About the number of cases Kehr returned without operating, a word as to mortality after operation.

In a recent communication which Professor Kehr sent me he gives me his statistics of 535 operations which were not complicated by diffuse suppurative cholangitis, sepsis, diffuse purulent peritonitis or cancer and in which it was not necessary to perform simultaneous operations on either the stomach, intestine, pancreas, liver, or kidney. His results were:

535 uncomplicated gallstone operations, with 19 deaths.....	3.5%
Divided as follows:	
237 conservative operations (cystostomies, cystotomies), with 5 deaths.....	2.1%
161 cystectomies, with 5 deaths.....	3.1%
137 choledochotomies and hepatic drainage, with 9 deaths.....	6.5%
535	3.5%

To these can be added:

114 complicated, with simultaneous operation on stomach, liver, intestines, pancreas, kidneys, etc., with 24 deaths.....	21%
71 cases of inoperable carcinoma of gallbladder of common duct and of liver, diffuse purulent cholangitis, and diffuse purulent peritonitis, with 69 deaths.....	97%

A grand total of

720 cases, with 112 deaths.....	15.5%
---------------------------------	-------

A physician can claim to have become a good diagnostician when he has learned to differentiate between hydrops and empyema of the gallbladder and an acute seropurulent cholecystitis and when he can determine whether a chain of symptoms is dependent upon obstruction produced by a stone, or is due to pressure from a tumor. This should be acquired by every practitioner.

THE MEDICOLEGAL ASPECTS OF AUTOABORTION.¹

BY

CHARLES GREENE CUMSTON, M.D.,

of Boston, Mass.

Tardieu defines criminal abortion as: "The premature expulsion, violently produced, of the product of conception, independently of all circumstances regarding its age, viability, and regular formation." In order to produce abortion, women less frequently resort, at the present time, to the various so-called abortive pills and mixtures. They have recourse to a much surer method, which consists in acting directly upon the ovum, either by tearing the membranes with a more or less pointed instrument or detaching them by an injection of some liquid forced into the uterine cavity. Now it may happen that a woman who desires to bring about an abortion does not seek aid from anybody else, and performs it herself; and that this is not unusual nor of modern date is evident if one will read Dr. Hugh L. Hodge's lecture on criminal abortion, published in Philadelphia in 1854.

Generally speaking, in these criminal cases, there are several individuals accused, namely, the woman who aborts and the accomplices in the abortion. In the present paper, however, autoabortion will be alone considered, and although hardly mentioned in the classic textbooks on medical jurisprudence, it is, nevertheless, certain that this type of criminal abortion is far more frequent than is generally supposed. Can a woman commit autoabortion by acting directly on the ovum? This is the question that is to be solved, and it is quite worth while to study it carefully, because criminal abortion is justly punished with great severity by the law. It is consequently not at all surprising that the lawyer

for the defense, in the interest of his client or clients, puts the above question to the medical witness, and if the latter admits the fact on principle, it is readily seen that he at once gives the defense a very powerful weapon and renders the prosecution very much more difficult.

In the first place, is it an easy matter for an instrument to penetrate the cervix without the use of a speculum? Vibert is of the opinion that the operation presents a certain number of difficulties; he tried it on 12 cadavers, using 1 hand, and failed each time, but he was always successful when both hands were used. He points out that the cervix recedes from the instrument, but that if it should be introduced, it will slip out with ease while the injection is being given, if it is not held in place with great care. This same authority was ordered to examine 3 women who said an abortion had been performed on them by another, who also admitted her crime, and he had the maneuver repeated in his presence. He was able to ascertain that the abortionist simply made a vaginal injection, and for this reason he concluded that the abortion in each case had been produced by other causes.

Now if individuals who are competent have such difficulty in introducing the canula of an irrigator within the cervical canal, it would naturally seem that these difficulties would be much greater for a woman desirous of performing an autoabortion. But from what I can gather, it would seem that women of the United States, at least, resort more frequently to the use of some rigid instrument, like a knitting-needle, a catheter, or a penholder, and less frequently employ the injection method. Personal knowledge of numerous cases met chiefly in consultation practice have led me to believe that autoabortion is being done among a large number of women both in the cities and country, a large percentage of these being married. In order that a woman may perform the operation successfully upon herself, certain conditions must be present, and it is necessary to demonstrate whether all these conditions are required to perform autoabortion, or if, on the contrary, the operation can be accomplished by nearly every woman.

From what I have been able to ascertain, it would appear that most women introduce the instrument within the uterus while in a crouching position and I am aware of only a few instances in which they succeeded when in the recumbent attitude. Without wishing to anticipate what is to follow, it may be said that no matter what position the uterus may have, the autoabortion will succeed in a large majority of cases.

It is difficult to say what may be called the normal position of the uterus and the opinions of the highest authorities on anatomy vary greatly, being almost in diametric opposition with one another. It is, however, quite logical to assume that the position of normal uteri varies from one subject to another. In several cases of autoabortion the uterus was found in a position intermediary to anteversion and retroversion, while in others it was in anteversion. In one case, the woman admitted that she first attempted autoabortion but being unsuccessful she resorted to an abortionist. But in this particular case a number of adhesions were found which immobilized the cervix against the rectum, making the cervical orifice difficult of access.

In other instances of autoabortion, the uterus was found retroverted and under these circumstances, when the retroversion is slight, this condition will greatly facilitate the entrance of the instrument into the cervix because the external os being directly in the axis of the vagina meets, so to speak, the instrument as it enters the vagina. Theoretically, a marked retroversion should create an obstacle to the instrument not easily overcome, because when the cervix is situated behind the symphysis and directed upward, the fingers introduced within the vagina come directly upon the posterior aspect of the uterus in Douglas' pouch, thus rendering the external os extremely difficult to reach. In order to

¹ Read by invitation at the Massachusetts Medicolegal Society, October 7, 1903.

get to it, the finger must be pushed perpendicularly behind the symphysis. In such cases of exaggerated retroversion, it is common to find the uterus bound down posteriorly by more or less dense adhesions which keep the uterus immobilized in this position, but nevertheless, it is more than likely that after several attempts a woman with a uterus in this position might be able to insert the instrument within the cervical canal.

To sum up, it may be said that the position of the uterus plays only a secondary part in the problem, but it cannot be denied that its position is not indifferent as to the ease and success of the operation. When the organ is markedly deviated and especially when it is bound down by adhesions in an abnormal position, autoabortion may become extremely difficult to accomplish, to such a point that it may be questioned whether in reality a woman could successfully carry out the operation with these anatomic difficulties present. This is certainly a delicate medicolegal point, the cognizance of which may be of great importance to the medical expert for either the prosecution or the defense. Uterine displacements are only important from the direction and position in which they place the cervix.

Admitting that a woman has a very movable uterus, easy to replace, it is necessary for the accomplishment of her crime that she can insert the instrument within the cervical canal when the distance or the condition of the cervix permits of it. The physiologic distance measured from the external os to the vulva varies from between 6 cm. to 8 cm. There are very short vaginas, measuring only about 5 cm., and there also large ones whose depth may attain 8 cm. or 10 cm., but it may be said that in a normal condition, a distance of more than 9 cm. is extremely rare. The average length may be placed at from 6 cm. to 8 cm.

Usually, a woman can easily reach her cervix, especially so when in the crouching position, because the uterus is pushed downward toward the vulva from 1 cm. to 1.5 cm. on account of the intraabdominal pressure, in which case the finger of the woman can easily reach it and place it in the proper position for the introduction of the instrument. In pregnancy the increase in size and the change of shape of the uterus must evidently influence its position. If one takes into consideration the classic descriptions given, it will be found that the fundus uteri projects slightly upward during the first 2 months of gestation. It remains in the pelvic excavation and undergoes a slight descent, which, according to some authorities is due to the increase in its size and weight, as well as to the pressure of the intestines which is brought to bear on the fundus. Other authorities uphold that such changes are far from constant and that one should take into consideration individual differences, which explains why in a large number of women the fundus uteri appears above the upper border of the symphysis during the first few weeks of gestation. The cervix does not undergo any descent or deviation and the organ does not point into the concavity of the sacrum. Charpentier has observed a number of cases in which the fundus uteri extended above the symphysis during the first 3 weeks of gestation and he has also found an exaggerated anteversion in primiparas which was sufficient to produce functional disturbances of the bladder from pressure.

Many authorities, especially the Germans, are far from admitting that retroversion with a descent of the uterus occurs during the first months of pregnancy. Schultze says that after the eighth week the enlarged corpus uteri may be felt in the anterior fornix, and personally, I have found this true in a certain number of cases. Necropsies performed on subjects dying during the first few months of gestation, in which the position of the uterus has been noted, are rare. One is recorded by His of a woman of 25, who hanged herself in the third month of her pregnancy. The uterus was anteverted and flexed. In another case, published by Braune,

the subject was a young female 8 weeks pregnant. The uterus was in retroversion, the fundus lying against the rectum, and presented a slight retroflexion. In this case the tissues were perfectly normal, and it is difficult to say why retroflexion and version had occurred.

In most cases, adhesions usually maintain the pregnant uterus in retroversion, but the normal position of the pregnant organ during the first 3 months is, as can be seen, very variable, according to the authorities.

Now it is during the first 3 months of pregnancy that abortions are usually undertaken. After the fourth month the uterus, having become too large to remain in the true pelvis, extends upward, drawing the cervix along with it, which causes the latter to become more distant from the vulva. The examining finger sometimes reaches it with difficulty, even when the perineum is depressed, and at this distance it would seem impossible that a woman operating on herself could reach the cervix. This is so, generally speaking, but in some cases the criminal may accomplish her end, and it is then that the talent of the expert must be called into play in order correctly to appreciate the conditions presented in the given case.

Regarding the condition of the cervix, we must consider both its external and internal os. The external os may be more or less hidden by the anterior lip, which may be found intact or lacerated, gaping or retracted, all of which points should be studied in detail. In 2 cases of autoabortion I have found a marked projection of the anterior lip, which proves that this is no obstacle to the accomplishment of the crime. If the cervix is intact without any old or recent laceration, it will dilate with ease, but if it is lacerated, 2 conditions must be considered. There is either gaping, which results from an ectropion of the entire mucous membrane, or on the other hand, there may be an atresia. In the first case, the result of an attempt to introduce an instrument is always successful, but in the second, it is doubtful whether the woman could accomplish her object. The difficulty would depend on the degree of atresia.

Beside the gaping produced by old cicatrices, this condition may also be found physiologically, and during the first few weeks of pregnancy it is not at all a difficult matter to introduce the tip of the exploring finger within the cervix. The conclusion that can be drawn is that during gestation, the condition of the cervix would facilitate the entrance of an instrument within the uterine cavity, and consequently render autoabortion an easy matter in most cases.

We will now suppose that the woman has been able to insert the instrument within the external os; it then remains for her to push it through the internal os. In accomplishing this 2 difficulties may present themselves, namely, a flexion of the corpus on the cervix, and, secondly, an abnormal decrease in its caliber. Flexion of the corpus on the cervix is almost always present in newly born females, but disappears as they grow; it is, however, met as a pathologic condition. When present, a slight bend of the canal at the internal os will exist, and this condition may prevent the instrument from continuing onward and puncturing the membranes. When badly directed, and if the instrument is a rigid one, it may enter the wall of the uterus instead of its cavity, and it is not at all improbable that certain accidents of this kind met in practice are due to this anatomic condition.

A flexion of the uterus may even present difficulties for a professional abortionist, and if lesions or traces of violence are discovered at the internal os it would be quite premature to conclude from these signs that another person had operated, should the pretext be given that a woman who had attempted autoabortion had failed on account of pain produced when pressure with the instrument was brought to bear upon the internal os.

The same considerations are applicable when the

internal os is abnormally narrow. Generally, however, its caliber is quite sufficient to allow a fairly good-sized catheter to pass through. It is quite true that it is inextensible and that its direction is contrary to that given to the instrument along the vaginal axis, but it should not be forgotten that the uterus being oftentimes movable, the woman can replace it with ease and retain it in a convenient position while inserting the instrument. In this position both the external and internal os will be found in the same line in the axis of the uterus, or nearly so, and consequently all that is required is that the instrument should be pushed directly onward in order that it may enter the uterine cavity. Auto-abortion will be as easily accomplished under these conditions as if performed by another person, on the condition that the uterus is freely movable. If the organ is held in a marked anteversion or retroversion by adhesions which cannot be stretched, the operation may be accomplished by a professional abortionist, but cannot be done by a woman herself.

Beside those difficulties of a purely material nature, which are few in number, there is another order, purely subjective in character, which would seem to have a great value. I refer to the mistake of situation of the instrument which certain women make, believing that they have the instrument within the uterus, when in reality they are only holding it against the external aspect of the cervix. They do not differentiate between the sensation produced by the instrument within the uterus and that caused when it presses on the outside of the organ. When, during an examination of the genital organs, a uterine sound is passed, the patient immediately notes a certain painful sensation, far different from that produced by the application of an instrument on the external aspect of the cervix. The instance mentioned by Vibert of the 3 women who admitted erroneously that they had been the victims of an abortion produced by an intrauterine injection, which in reality had been only an ordinary vaginal irrigation, is a startling proof. These women had certainly never distinguished between the sensations produced in the vagina and cervix from the one caused by the penetration of an instrument within the uterine cavity. The latter is never forgotten when once it has been felt, and in every instance in which a woman has not distinctly felt a pricking sensation in the lower abdomen when puncture has been resorted to, or the sensation of a hot fluid extending upward within the body when an intrauterine injection has been employed, the greatest reserve should be maintained by the expert, and if possible the experimental proof should be resorted to. When an injection is used for the purpose of bringing on an abortion, women when performing the operation upon themselves usually employ one of the hard rubber ends which go with any fountain syringe, and when once the tip is inserted beyond the internal os all that is necessary is that she should hold the tube in place and allow the liquid to enter the uterine cavity.

From a study of a number of cases in which the women admitted having performed an auto-abortion, many of them being married in easy circumstances, and others belonging to the more ignorant class, it would seem to me that a woman need not be very familiar with the anatomy of her genital organs in order to accomplish quite easily the induction of a miscarriage. When a woman wants to rid herself of a fetus, it makes very little difference what social condition she may occupy, because in all ranks of life the woman will have the same criminal design, and when she is not fully aware how to proceed in the act, some friend, usually of the female sex, will be found who can give a detailed account of the *modus operandi*. To quote cases would be useless, but I can affirm that I know professionally a number of married women who perform auto-abortion once a year at least, and in 1 or 2 instances they resort to the operation several times in the course of 12 months.

From what I have said, I think it can safely be admitted that it is often possible for a woman to introduce a foreign body through the cervical canal into the uterine cavity, and the logical consequence is that she is able to perform an auto-abortion. For this reason I can not agree with some of the statements made in our best and most modern textbooks on legal medicine, a few quotations from which I will make. In Witthaus and Becker's *Manual of Jurisprudence*, Vol. ii, 1894, Cameron says: "Women often attempt to pass such instruments into the uterus themselves, and occasionally they succeed, but are very apt to injure themselves seriously." This is also the opinion of Herold, who makes a similar statement in his *Manual of Legal Medicine*, published in 1898. In the fourth edition of Wharton and Stillé's *Medical Jurisprudence*, it is stated that: "In some instances the woman seeks to rid herself of her burden . . . by the introduction of instruments into the womb. These attempts are often unsuccessful when made by the female herself, and even an ignorant accomplice." I am perfectly willing to grant that women do injure themselves by attempting auto-abortion, and I know of several instances in which it has been attempted and had to be given up on account of the impossibility of introducing the instrument within the cervical canal, but in each case the medical witness must make a special study, because certain details will often be of greater use to him than the knowledge obtained from the textbooks which indicate only the means by which the crime is accomplished.

When a case of auto-abortion has been alleged, the medical expert in his examination need pay very little attention as to the distance existing between the cervix and vulva, and although displacements of the uterus have their importance, they can be of no absolute indication one way or another. Perhaps the most important condition is that of the presence of adhesions, because when they are present, binding the uterus either anteriorly or posteriorly, it is probable that the woman could not introduce an instrument within the external os. Old, thick, and fibrous adhesions act like ligaments and solidly retain the uterus in its abnormal position, and when this abnormal position is well marked, the expert will probably not be wrong in affirming that a second person has been required to accomplish the abortion.

Atresia of the cervix, when it exists, should be taken into account, but its value against the possibility of auto-abortion, is only a relative one.

It is also of importance to ascertain the intellectual condition of the accused, because it is probable that an intelligent woman will take in the situation better and be able to accomplish her end with more address than a woman endowed with less brains, although there must be many exceptions to this rule. Besides, an intelligent woman will be more daring and will be less liable to tell her secret than will the unintelligent one. In all questions of criminal abortion, the smallest details will be useful, and it is often by little facts that the discovery of the truth is attained; and in conclusion, I would once more repeat, that in the question of auto-abortion I cannot subscribe to the opinion usually advanced in the wellknown works on medical jurisprudence. Without taking into consideration the arguments that the defense might be able to extract from what has been said, I simply am desirous of throwing light on the question which, up to the present time, has been badly studied. The medical expert should always have present in his mind that his first duty is to discover by all the means possible the proofs or evidence of some description of an accomplice; but he should also bear in mind that in the case of a criminal abortion an accomplice is not always necessary, and that often a woman of only moderate intelligence and ability will attempt to rid herself of a pregnancy when the latter is injurious either to her interests or to her reputation.

POSTOPERATIVE INTESTINAL OBSTRUCTION.*

BY

A. M. POND, M.D.,
of Webster City, Ia.

Almost the first question that arises after the first 24 hours following an abdominal section is, Has the patient passed gas or evacuated the bowels? If answered in the affirmative the surgeon at once assumes that all is well, and a favorable prognosis is given.

There are few distressing complications that perplex the surgeon more than postoperative intestinal obstruction; few conditions require the intelligent conception of the cause producing the same and call for the deliberate and well-directed action to relieve.

This condition occurs as a complication in about 5% of all abdominal operations, and is of sufficient frequency to demand our earnest study into the cause producing this grave state, as well as our increased efforts to prevent or successfully relieve.

Intestinal obstruction following operation, quite naturally divides itself into the following classification, as to cause:

1. Impairment of physiologic function. Under this head might be mentioned (a) impaction, due as a rule to improper preparation; (b) paresis, or disturbance of motor nerves due to prolonged manipulation and exposure to reduced bodily temperature; (c) lowered resistance following hemorrhage; (d) atony superinduced by alcoholism, diabetes, tuberculosis, Bright's disease or any constitutional condition that tends to lower the general vitality.

2. Pathologic processes such as (a) inflammatory impairment of function; (b) destruction of parietal peritoneum as in breaking down adhesions; (c) intoxication by pus, as in general septic peritonitis; (d) thrombosis of mesenteric veins, following contusion.

3. Mechanical obstruction due to (a) adhesions to stumps that are improperly covered; (b) velamentous or adventitious bands arising from the parietal peritoneum following a general septic peritonitis; (c) omental rents or tears; (d) accidents to the sutured wall; (e) presence of gauze sponges, instruments, or other foreign materials accidentally introduced during operation and overlooked before closing.

In presenting this important subject then, for consideration, it will be my pleasure to follow closely the form as outlined in the classification given, and in taking up the forms arising as due to impairment of physiologic function, the first to be considered is (a) impaction, and as stated, this as a rule is due to improper preparation. Cases of such severe gravity as to demand immediate operative interference will not permit of the thorough preparation that a case of deliberate and well-planned operation would receive; however, we can take some steps toward the accomplishment of bowel evacuation, even in the most grave conditions. A few years ago Dr. Henry T. Byford, of Chicago, gave expression to a routine plan that will especially apply to this class of cases; it consists in the administration of 3.8 cc. to 7.5 cc. (1 dr. or 2 dr.) of the aromatic fluid extract of cascara sagrada before anesthesia, or immediately following a return to consciousness; this does not act as a cathartic, but as a general intestinal tonic and stimulant, and in the vast majority of cases is most gratifying in its action. When there is not an attempt made to secure a bowel movement until after operation, the shock, together with a lessened activity of the intestinal wall following anesthesia, oftentimes makes this exceedingly difficult to accomplish, and not infrequently obstruction will occur; at times the impaction can be distinctly felt as a tumor, if the abdominal walls are not too thick. All of the symptoms of mechanical obstruction may be present, namely, vomiting, distention, anxious

facial expression, pulse and temperature slightly elevated, and the condition may occasion serious concern.

The temptation is great just at this time to be too energetic in attempts to secure bowel activity by the administration of cathartics; a much wiser plan to pursue is, in the absence of grave conditions, to wait, so long as the discomfort of distention is not distressing or the vomiting annoying, and this usually becomes less, and subsides with the recovery from shock. General tonics and stimulants will also tend to cut this period short by increasing the general resistance. Strychnia, 2 mg. ($\frac{1}{80}$ gr.), may be administered with or without brandy, as indicated. Obstruction due to impaction occurs from 2 general sources, first, in those who were habitually constipated and in whom the intestinal tone was much below normal before operation, thus, in consequence of the shock, what tone they did possess is considerably lessened; and, second, in those cases in which there has been a previous septic peritonitis of a more or less local character, and there is a subsequent stenosis from some encroaching adventitious bands, the fecal current comes down to the stenosis and occasions obstruction. It is well to remember that obstructions due to impaction occur only in the large intestine, and when not due to any lessened lumen of the canal, can as a rule be located where the fecal current is apt to be retarded, as in the sigmoid flexure or other flexures at or near the cecum.

In considering (b) paresis in this connection, I shall deal only with the local disturbance of the motor nerves, such as is occasioned by excessive manipulation or exposure to reduced bodily temperature, since it is only this form of paresis that follows operative procedure. It is a wellknown physiologic fact that the fecal current is dependent wholly upon the vermicular action of the bowel, if, then, for any reason this contraction is impaired or destroyed by reason of disturbance in circulation or motor nerves, the current stops at the exact point of the disturbance. Von Wahl¹ first called attention to this apparent paradox, that in intestinal obstruction when the tympany is most marked, the coil in which the obstruction exists is the most tympanitic, for it is this very coil which, through the disturbance of its motor nerve supply, is first distended by gas from fermentation of its contents by reason of stagnation. As a rule this condition occurs in the large intestine, but may be present in the small bowel when disturbances are sufficient to interfere with either its circulatory or nerve supply; fortunately this complication is largely preventable by using gauze pads wrung out of a hot (110°) decinormal salt solution in handling the intestines, and when compelled to eviscerate, carefully enveloping the protruding coils within towels wrung out of the same solution; the artificial heat, together with the stimulation of the chlorin of the sodium chlorid, has a tendency to maintain the normal conditions of the circulation upon which the tone of the motor nerves wholly depends. The cardinal symptoms of paresis are tympany and distention, with enormous accumulations of gas. In many instances the high enema of decinormal solution will readily relieve the distress when in the large bowel. Dr. Howard A. Kelly, of Baltimore, suggests the use of the cautery point heated to a dull red and passed over the surface of the abdomen, just singeing the tops of the short hairs, but not coming in contact with the skin.² I have used this in cases of my own with marked benefit. Dr. Clement Cleaveland, of New York, advises the use of oxygen gas.³ A high rectal tube is passed well into the bowel and connected with the tube of the water bottle accompanying the cylinder of gas, and then the oxygen is liberated very slowly until the patient complains of discomfort, when it is cut off and the connection with the water bottle severed, but the rectal tube remains. He reports several cases in which prompt evacuations occurred, and I have used it with gratifying results.

* Read at the Semicentennial Meeting of the Dubuque Medical Society, June 18, 1903.

The obstruction due to (c) lowered resistance is so closely allied to the foregoing form in its pathology that I will not weary you by a repetition, further than to state that while the former is apt to be a local disturbance of function, lowered resistance is usually due to hemorrhage, and in consequence the condition may be general—the nerve stimulus is present, but the responsive ability of the muscle is lessened. There is a lack of tonicity and an inability to pass the contents of the bowel, whether gas or feces. Like the foregoing condition, it can in a great measure be prevented by carefully conducting the operative procedure, securing all bleeding points at once upon discovery, and being sure that no oozing exists before closing the abdomen. In the event that hemorrhage sufficient to produce the impaired state occurs in spite of all precaution, much of the tonicity can be restored by filling the abdomen with hot solution of adrenalin chlorid in a decinormal salt solution in the proportion of 1–1,000, or 1 minim of the solution of adrenalin chlorid to each 2 ounces of decinormal salt solution. This increases the intestinal blood-pressure very markedly and stimulates peristalsis.

(d) Atony of the intestine due to some predisposing cause is the most obstinate form of obstruction arising under the head of impairment of physiologic functions. These cases usually occur following operations on persons who have indulged moderately in the use of alcohol, or who are suffering from some wasting process, such as tuberculosis, diabetes, or Bright's disease. Everything may go on favorably for the first 24 or 36 hours after operation, bowels and kidneys move thoroughly and well, and suddenly, without warning, the intestines relax and cannot be stimulated to action. The following case occurring in my practice is typical:

The patient, F. D. C., aged 41, is a stock-buyer and auctioneer. Family history is negative. He had typhoid fever 20 years ago, and gives a history of drinking on an average 1 pint of whisky daily for 12 years; frequent intoxication by periods. He was taken with abdominal pain August 8, 1901. In the early morning of August 10, 1901, I saw him with the attending physician, Dr. C. I. Eberle, of Webster City, Ia. Examination demonstrated a marked tumor in the right iliac fossa, tender on pressure; temperature 98.6°, pulse 80. A diagnosis of appendicitis was made. Immediate operation was denied. His condition grew rapidly worse, until at 5 p.m. pulse was 120, temperature 102.6°.

Operation.—A very large appendix, $3\frac{1}{2}$ inches long and $\frac{1}{2}$ inch in diameter, appearing not unlike a Frankfurt sausage, was seen. The mesoappendix was much thickened and hypertrophied. A hard mass observed in the caput coli proved to be a large quadrilateral gallstone with facets on 2 sides. The appendix was removed, the caput coli incised, and then sutured after removal of the gallstone. Subsequent history was uneventful for about 36 hours; bowels moved freely August 11; pulse and temperature were normal. About noon on August 12 the patient complained of discomfort, and was found to be slightly tympanitic. A high rectal enema was ordered, which up to 4 p.m. had no effect. Gastric lavage gave temporary comfort. An enema of magnesium sulfate 15 gm. ($\frac{1}{2}$ oz.), turpentine 30 cc. (1 oz.), glycerin 30 cc. (1 oz.), in a pint of warm water, was ordered through a high rectal tube, with no result. At 9 p.m. tympany increasing. Calomel $\frac{1}{2}$ gr. doses, followed by magnesium sulfate $\frac{1}{2}$ oz. in hot water, was ordered with still no result. Tympany was intense, pulse rapidly increasing, temperature 101.6°. Wound was examined and found clean; 2 stitches were cut; there was no fluid. The patient died at 12.10 a.m., August 13, 1901. Autopsy revealed enormously distended coils of intestine, ruptured diaphragm, and a small amount of dark blood behind the liver in the lesser peritoneal cavity. This man unquestionably died of tympany, due to atony of the entire gastrointestinal tract.

(a) The impairment of intestinal action due to pathologic process is most commonly met in the acute inflammatory involvement of the different coats of the intestine and it varies in intensity according to the degree of inflammatory involvement. If the mucosa alone is impaired the condition as a rule subsides in from 24 to 36 hours without intervention, relying wholly on rest. As the process extends it involves the muscularis tunica and prevents peristalsis. The wave of action will reach the impaired section with usual energy but the circulatory disturbance of the muscular fiber has impaired its tonicity and it fails to respond to the nerve

impulse and beyond the point of inflammation, all action is suspended. When the process involves all the tunics, the condition is relatively exaggerated. This condition does not often occur primarily, but is dependent upon acute inflammatory disturbance in its immediate vicinity, and with which it has intimate relationship as in acute inflammations of the appendix; the caput coli is often involved. Especially if the offending member be reflected behind the cecum, should the inflamed appendix be deflected to the left, it will be found adherent to the neighboring coils, jejunum or ileum and the tunics of that intestine will suffer secondary involvement. The same conditions are to be noted in acute inflammatory disturbances of the ovaries, gallbladder, mesentery, in fact any of the abdominal contents. After the removal of the provoking cause, the intestine suffers from traumatism to a greater or less degree and the condition of secondary hyperemia may not rapidly subside. The symptoms will be vomiting, distention, increased temperature and pulse-rate accompanied by tenesmus if in the large intestine, and by nausea and vomiting if in the small intestine. It is obvious that all cathartics must be withheld, an impaired intestine must have rest. If tenesmus is present it is safe to assume the location is in the large bowel and the use of oxygen gas will relieve to a great extent the circulatory stasis, and peristalsis will be rapidly established. If the trouble is in the small intestine it is best to withhold all food and drink by mouth, even water unless it can be taken without nausea, and to feed per rectum predigested food. If food is given by the mouth it cannot get beyond the inflamed portion of the bowel and will only ferment and cause distress or else be rejected. If the food given by the rectum should cause any disturbance it can at least be removed without disturbance.

(b) The destruction of the visceral peritoneum is incident to conditions in which adhesions are present, in freeing them the investing membrane is sacrificed. When this occurs the traumatism is pronounced, the circulation is greatly impaired, hyperemia and edema occur and the peristaltic wave cannot pass the injured point. The mucosa is also greatly swollen, lessening the lumen of the canal. If the destruction of the visceral membrane cannot be repaired by sutures it is best to rest the injured organ in order that fresh adhesions may form and the circulation be reestablished. So long as the patient shows no serious symptoms other than obstruction, the impaired bowel demands rest. The tympany and distention can often be controlled by gastric lavage and this may be used as frequently as demanded for the patient's comfort. I feel sure that I lost the patient in the following case by the injudicious use of a cathartic.

V. B., a male, aged 13, was taken sick with acute colic August 3, 1902. I saw the patient in consultation August 6. The temperature was 102°, pulse 130. Abdomen was rigid, and there was acute pain in the right iliac fossa. There had been no bowel movement since August 3. There was vomiting and tympanites. A diagnosis was made of acute suppurative appendicitis.

Operation was performed at 5 p.m., August 6. The appendix was found much enlarged, turned backward, and adherent to the cecum. The cecum was adherent to the parietal peritoneum, and in order to deliver the appendix was broken down under the guidance of the eye. The cecum was greatly swollen, and the adhesions fixing the appendix to the cecum were severed, leaving a triangular space $1\frac{1}{2}$ inches wide at the base and 2 inches long, denuded of parietal peritoneum. After removal of a suppurating appendix an attempt was made to bring the edges of the investing membrane together, but without success, due to the great size of the cecum and the inability of the membrane to hold suture. The denuded cecum was wrapped in a gauze pad wrung out of a hot sterile salt solution, and the abdomen was filled with a quantity of the solution at a temperature of 108°. This floated the intestines in place, and the omentum was drawn down under them as much as possible. The wound was closed, and patient put to bed with the feet elevated from 12 inches to 18 inches. Immediately after consciousness was restored, a tablet of calomel .013 gm. ($\frac{1}{4}$ gr.) was ordered every 30 minutes, until the bowels moved freely. Evacuation occurred about 3 a.m., August 7. Up to this time

the pulse was good, and there was no nausea. At 9 a.m., the temperature was 99.2°, pulse 86. At 7 p.m., the temperature was 98.6°, pulse 84. There was no bowel movement. On the morning of August 8, the temperature was 98.6°, pulse 84; no bowel movement. Calomel .013 gm. ($\frac{1}{4}$ gr.) was ordered every 30 minutes for 5 doses, to be followed in 4 hours by a high rectal enema. At 9 p.m., the temperature was 100.2°, pulse 110; no bowel movement. The patient complained of tympany; there was no vomiting. I ordered an enema of glycerin 30 cc. (1 oz.), turpentine 30 cc. (1 oz.), asafetida 30 gm. (1 oz.), and water 1 pint. On the morning of August 9, the temperature was 102.1°, pulse 120. No bowel movement; tympany sufficient to embarrass respiration. The cauterization was tried over the abdomen without success. Oxygen per rectum had no effect. At 1 p.m., the temperature was 102.2°, pulse 125. Cold applications were applied to the abdomen. At 3 p.m., 2 stitches were cut and a quantity of bloody serum escaped. At 9 p.m., vomiting was almost constant; the vomitus was of a green and yellow color. Temperature was 102.6°, pulse 130. Patient died at 3 a.m., August 10.

This unfortunate case taught me much, but the complete subsidence of abnormal pulse and temperature for 48 hours after operation convinces me that the intestinal obstruction was due to the impaired cecum, and that death was due to indigenous peritonitis as described by Flexner.⁴

(c) Obstruction of the bowel due to the intoxication of septic material, is the form met in cases of diffuse septic peritonitis, and results from the absorption of the toxins, ptomaines, and albumoses incident to the suppurative process. The visceral and parietal peritoneum are invested with a thin layer of fibrinous deposit. This most distressing and nearly always fatal complication must be treated largely by prophylaxis. This is best accomplished by the improved operative technic, which leaves no dead spaces, checks all hemorrhage, and protects the peritoneal cavity from contamination by liberal packing of gauze, before evacuating an abscess or breaking down adhesions, and which rigidly enforces all aseptic and antiseptic requirements. Flint⁵ mentions the depurative action of the liver in peritonitis, and, no doubt, thorough purgation would eliminate the elements of infection, but these very elements have caused an intoxication of the nerve supply of the intestine to the extent that purgation is rarely accomplished, and when successful is more often the result of a high enema containing magnesium sulfate and turpentine with other combinations than it is through the administration of evacuants by the mouth.

(d) Thrombosed mesenteric veins or shrinking of the mesentery following acute inflammation. This condition was first described by Virchow under the name of "peritonitis chronica mesenterialis." This occurs either as an extension of the inflammatory process or as a direct result of trauma. In either case the pathology is the same, increased circulation of the part, congestion, stasis, formation of pus and consequent gangrene of intestine. Riedel⁶ has reported 8 cases with complete pathologic findings. The extension of inflammation occurs at the site of the intestinal disturbance and is quite common at or near the cecum subsequent to acute appendicitis, but may occur in the mesentery of the small intestine at or near the sigmoid. The same condition may follow a trauma of the mesentery incident to operative procedure.

Obstruction due to mechanical agents may follow operation and differ materially in symptoms from cases due to impaired physiologic function or to pathologic processes. As a rule the pulse-rate is lowered instead of elevated, the peristaltic wave can often be seen through the abdominal walls in thin patients, vomiting occurs earlier, and is at first the stomach contents; this is followed by a yellowish brown material and then by a dark brown, not unlike the vomitus of septic peritonitis.

In fact we only find this characteristic vomitus in these two conditions, the point of difference and frequently the only distinguishing feature between them being in the pulse-rate and temperature. In septic peritonitis the pulse-rate is very rapid and increases until no arterial

impulse is perceptible and a "flowing pulse" is noted. The temperature is usually very high. In mechanical obstruction the temperature may be slightly elevated, but seldom reaches a point above 100°; the pulse-rate is diminished, ranging from 50 to 70 per minute.

(a) Adhesions to the intestines from incompletely covered stumps are frequent causes of postoperative obstruction. They may occur from 2 weeks to as many months or more after operation. It is surprising what a serious obstruction may occur from an apparently insignificant adhesion. The following case is illustrative:

Mrs. A. M., aged 29, gives a history of a miscarriage in September, 1899, which was followed by a feeling of tenderness in the left side. On December 9, she had a chill followed by rising temperature; there was no abdominal tenderness. On December 20, temperature was 102.6°, pulse 124, abdomen was tender and enlarged in the left lower quadrant; vaginal examination revealed a mass in the left fossa.

Operation.—December 21. Left pyosalpinx was found and the left ovary removed. The tube stump was tied to the broad ligament and sutured with continuous sutures from the left ligament to the cornu. The history was uneventful until the twenty-second day after operation; the patient was sitting up in bed when she complained of an acute colicky pain in the lower abdomen. Vomiting occurred, the temperature was 100°, pulse 62. An enema was ordered and quite a copious movement followed. It might be pertinent to state in this connection that this is often deceiving from the fact that the opinion will be that obstruction does not exist or the bowel could not move. The bowels do not evacuate their contents only from the adhesion down and if this should be in the small intestine it is likely to be misleading, however a little time will clear up the situation. Vomiting increased and the ejecta became very dark; the peristaltic wave was plainly perceptible. Diagnosis was made of mechanical obstruction above the cecal valve. A second operation was performed; the ileum on its free border was found adherent to the left cornu of the uterus, causing an acute angle obliterating the canal. This slight adhesion was sufficient to obstruct completely the fecal current. The adhesion was divided and the stump covered by a narrow fold of the reflected peritoneum. Recovery was uneventful.

(b) Velamentous bands may proceed from parietal peritonitis or some of its reflections and hold captive a loop of intestine. These bands are particularly prone to form after a general septic intraabdominal condition and are caused by the thin viscid coating of fibrinous exudate, which so commonly invests the intestine during an extensive suppurative process. This fibrinous exudate becomes intimately related to some adjacent tissue and receives a circulatory supply, which causes it to become an organized tissue, gradually becoming firmer and firmer, until the lumen of the bowel is obliterated and the intestine held fast. The following case illustrates the typical form:

Mrs. D. Y., November 24, 1901, was taken with an acute intestinal pain, vomiting, and slow pulse. No diagnosis was obtainable. The patient vomited at intervals all night, vomitus being dark brown, almost black. She had a slow pulse; temperature was 99.6°; there was slight tympany. The absence of an increased temperature and pulse and the character of the vomitus led to a diagnosis of mechanical obstruction of the small intestine. Operation was suggested, but opposed. Several other physicians followed, but no benefit was obtained. Atropin had been tried by one of these in .032 gm. ($\frac{1}{4}$ gr.) doses. December 13, or 18 days after the obstruction occurred, I was asked to operate. During this time no gas or feces had passed and the patient had vomited feculent material.

Operation.—December 14. The intestines were full of gas and considerable difficulty was encountered in keeping them in the cavity after an incision was made just below the transverse colon. On the right side the imprisoned intestine was found held by a velamentous band of fibrous origin attached to the parietal peritoneum. This was severed and the bowel liberated. At first it was thought that a stricture was formed and resection was considered, but by careful manipulation gas was forced through, and therefore the abdomen was filled with hot saline solution and closed. Recovery was uneventful. It might be of interest to note that in March, 1900, about 20 months previous to this operation, I operated on this same woman for ruptured ovarian abscess and evacuated an enormous quantity of pus from the abdominal cavity. The intestines were covered with thin fibrous exudate and a large amount of flocculent material was removed. Another point of interest in this case is the length of time that elapsed from the time of obstruction to operation.

(c) Incarceration of loops of intestine in omental rents or tears usually gives rise to symptoms shortly after

operation. Many causes are assigned for the occurrence of this condition, the chief of which is probably the Trendelenburg position. This gravitates the intestine and omentum into the upper abdominal cavity. To avoid these complications it is best to restore the patient to the horizontal position before suturing, and to fill the abdomen with hot sterile saline solution, which tends to float the intestines into their normal relations; and lastly, to cover the bowels with the omentum as completely as possible, and if rents or tears are discovered, to suture them carefully with fine catgut before closing the wound. Obviously the treatment is reopening the abdomen and freeing the loop of intestine. Too much emphasis cannot be put upon the early release of the bowel; gangrene of the intestine has been reported after 26 hours. If the symptoms of obstruction immediately after operation are present, it is much easier to reopen the wound and seek the cause than to combat graver complications occasioned by delay through hoping that release will occur unaided. This hope is unfounded. These cases confront the surgeon with 2 propositions: (1) The gravity of secondary operation is not to be depreciated; (2) if left alone death will invariably result. Hence, the plain duty is to offer the patient the only chance for life, as delay will result disastrously.

(a) Fortunately, accidents occurring to the sutured wall after closure are comparatively rare. The following case is, however, of interest:

Mrs. M. D. A., aged 41, was operated upon April 12, 1900, for left cystic ovary. It was a simple case with no adhesions. The ovary was delivered through a small incision, and removed with the corresponding tube; the broad ligament was sutured with continuous sutures; there was no pedicle. Peritoneum was closed with a running suture of catgut, continued through the muscular layer, and the skin was secured by a subcutaneous catgut suture. Considerable vomiting followed the anesthesia. Cascara was given at once after consciousness was restored. Vomiting continued through the night; there was no indication of bowel movement. Another .60 cc. (2 oz.) of cascara was administered. At 11 a.m., April 13, she was still vomiting a yellowish-green material. I ordered calomel, 6 mg. ($\frac{1}{10}$ gr.), every 30 minutes. At 2 p.m. a dark brown fluid was vomited; there was abdominal distress but no bowel movement. Pulse was 60, temperature 99°. I suspected obstruction of the small intestine, but could not account for its occurrence so soon after operation. The patient complained of the abdominal binder being tight, and it was therefore loosened. After removal of the dressing it was found that the wound had parted throughout its entire extent, and numerous coils of the intestine lay spread out over the surface of the abdomen. They were lustreless and congested. I sent for sterile gauze pads, needle and needleholder, and silkwormgut. The protruding coils of intestine were immediately enveloped in towels wrung out of hot saline solution. On account of the distressing nausea and vomiting, it was deemed unwise to anesthetize again, so without anesthesia the intestines were replaced, a through-and-through silkwormgut applied, and a high enema ordered.

A free evacuation rewarded the procedure, and recovery was uneventful.

From the foregoing it will be seen that the treatment of postoperative obstruction depends very largely upon its cause. In cases due to impairment of physiologic function, stimulation of peristalsis should be the object aimed at, and it will probably respond to any medication that will secure such stimulation. An enema, medicated or plain, is by far the simplest treatment and the easiest of administration. If it does not prove effectual, the application of the cautery over the abdomen should be tried. The use of cathartics is very questionable, since the nerves which stimulate peristalsis are already impaired and will not readily respond, and when they do, it is at the expense of more energy. The condition becomes more grave, and increased medication is required to secure each succeeding evacuation. Rest does much in this condition, and if the patient is doing well with the exception of bowel movements, it is not wise to be too energetic in attempts to secure evacuation.

In cases due to pathologic processes, cathartics are positively counterindicated. The treatment should consist in

lessening the peristalsis and securing rest. Batsch⁷ reports 3 cases in which the patients were treated by atropin given hypodermically in $\frac{1}{12}$ gr. doses, without toxic results, 2 patients recovered, 1 patient was operated upon, and the trouble was found to be due to mechanical obstruction. Luttgen⁸ reports 4 cases, with 3 recoveries and 1 death. Marcirnoueski⁹ reports 2 cases with recovery. Atropin owes its application here to 2 therapeutic properties: 1. Its sedative action in all spasmodic conditions in which it stands second only to opium and possesses the superior advantage of not being constipating. 2. Its action on the circulation, dilating the bloodvessels and relieving stasis and congestion.

The use of oxygen is especially valuable in this class of obstruction, since it lessens the formation of ptomaines and albumoses by supplying the congested blood-current with its vitalizing element, the same as it would receive from the inspired air through the pulmonary circulation. And is it not possible for the blood in this location to give off its carbon dioxide in exchange for oxygen supplied as suggested, much the same as it does in circulation through the lungs?

If this be true, it certainly is better prepared to participate in the work of repair demanded in the injured intestinal wall. In mechanical obstruction there is just one rational mode of treatment—to release the intestine—and this can only be accomplished by operation, and the earlier it is undertaken, the more favorable prognosis can be given.

SOME FEATURES OF THE EPILEPTIC ATTACK.¹

BY

B. ONUF (ONUFROWICZ), M.D.,

of Sonyea, N. Y.

Pathologist to the Craig Colony for Epileptics; Formerly Neurologist to St. Catherine's Hospital, and Consulting Neurologist to the Jewish Dispensary, Brooklyn.

One who is not in frequent touch with epileptics is very apt to get an erroneous, or I might say, diagrammatic conception of this syndrome. This has especial reference to the epileptic seizure. Many textbooks speak of the so-called typical epileptic attacks, and the young practitioner makes desperate efforts to get hold of such for his instruction, but to his great regret he cannot find them. Féré has justly pointed out that there are almost as many forms of attacks as there are epileptics. Even in the same individual great variations between the different attacks are found.

From a medical point of view, it would appear very important to find characteristics that stamp an attack as epileptic and to secure in general definite points typical of epilepsy. However, here again we are baffled; there is not a single symptom that is characteristic of epilepsy and it is only by familiarizing ourselves with the great variety of forms in which the disease can show itself, and by constantly comparing them with the picture and course of other diseases, that we can arrive at a correct diagnosis.

A very important point is personal observation of the epileptic attacks. The value of such observations is proportionate to the experience and knowledge of the observer since an inexperienced observer may remain in doubt, or come to the wrong conclusion, even if he sees

¹ Read at the twentieth annual meeting of the New York State Medical Association, New York, October 19-22, 1903.

the seizure. Therefore, familiarity with the various forms in which the epileptic attack may manifest itself is of extreme importance.

With such a number of epileptics as are found at the Craig colony, which at present amounts to over 800, the opportunities for seeing epileptic attacks are unusually favorable, and the writer has made use of these opportunities to study such attacks and make careful notes of them.

I shall now discuss the points that this study brought out, viz.: 1. The initial cry. 2. The condition of the pupils. 3. The manner, grouping, and distribution of the spasms. 4. The state of consciousness. 5. The condition of the tendon-reflexes.

1. *The Initial Cry.*—That erroneous conceptions are prevalent regarding the nature of the initial cry in epileptic seizures, I had recently an opportunity to observe. A physician making a visit at the colony was anxious to see some attacks. About 5 steps from him a patient uttered the epileptic cry, which was followed by a very grave convulsion. I called the doctor's attention to it. He mentioned later with regret that the seizure had lacked one classic feature, *i. e.*, the cry. In accordance with what he had been taught, he had expected a shrill, loud cry, and, therefore, did not recognize the real cry, which was a low, protracted, tremulous groan. This groan-like feature of the cry is indeed very frequent. In constant association with epileptics, the ear becomes so trained to it that the ominous character of the groaning is immediately recognized.

It is now generally accepted that the cry is not one of surprise or fear, but a purely spasmodic phenomenon, due to the spasm of the respiratory muscles driving the air through the spasmodically contracted glottis. The bleating-like tremor of the cry is explained by the assumption that the initial spasm is not purely tonic, but slightly clonic, *i. e.*, with slight rhythmic relaxations of the spasm.

2. *The Pupils.*—It has long been taught that dilation and immobility of the pupils constitute a constant symptom of the epileptic seizure, and this sign has been pointed out as one by which the epileptic seizure can be distinguished from the hysterolepileptic, in which the pupil was said to be normal, both in size and in reaction. Recent observers have shown, however, that this distinction does not hold true, inasmuch as immobility of the pupil has been observed in seizures which were undoubtedly hysterolepileptic.

Moreover, it is certain that in the epileptic attack the pupil is not invariably dilated and not always immobile. I have seen at least 2 cases in which it was not dilated in the convulsive stage. In one of these the attack was very severe and the pupils were examined toward the beginning of the clonic stage. They were contracted rather than dilated. In the other case the attacks were mild and of short duration, but followed each other in rapid succession. In this case the pupils behaved quite varyingly. In some attacks they were moderately dilated and would react. In others the caliber of the pupils changed several times during the attack, reacting at one time, not at another.

On the whole, the degree of dilation of the pupils gives a measure of the severity of the attack, but to this there are exceptions, as above noted.

The condition of the pupils at the beginning of the attack and again in the postconvulsive, *i. e.*, stertorous stage, is not, as a rule, mentioned in the textbooks. However, some authors have called attention to it.

In one case, a nurse was instructed by me to watch the pupil carefully at the beginning of the seizure and he reported that, just as the attack began, the pupils became extremely small, then all at once they jumped, as he said, becoming very wide. This extreme contraction of the pupil directly at the beginning of the attack was observed also by Siemens and Féré. It is, however, frequently missed.

At the beginning of the stertorous stage, immediately after cessation of the convulsions, the pupils may again be found contracted, as I had occasion to observe in a number of cases, but the contraction is not so marked.

3. *The Character, Distribution, and Grouping of the Convulsions.*—In discussing the convulsions of the grand mal attack, I shall begin with literally quoting a description of an attack as given by a wellknown author, Dr. Charles L. Dana: "The attacks," he says, "begin in half the cases with a peculiar sensation called aura. Often also a loud cry is uttered and the patient falls unconscious to the ground. The face is pale, the eyes are open and turned up and to one side, and the whole body is in a state of rigidity or tonic spasm. The arms are slightly thrown out from the trunk, the forearms are flexed, the fingers clinched or flexed in other ways, and the legs and feet extended. This tonic stage lasts for 15 to 20 seconds. The face becomes congested and livid from compression of the veins of the neck and stoppage of respiration. Gradually jerky movements of the face and limbs begin and the stage of clonic spasm sets in. The trunk and limbs are now alternately flexed and extended with violent shock-like convulsions. The facial and eye muscles twitch, the saliva collects in the mouth, and as the tongue is often bitten, it becomes stained with blood. The movements are sometimes so violent that the patient is thrown about the bed or floor, and occasionally a limb is dislocated, usually the shoulder."

This description is fairly typical of what we are usually taught of the course of an attack of grand mal, and was therefore selected for discussion. Let us single out some features:

In the first place, the eyes are described as open and turned up and to one side and the head as thrown back and turned to one side. This is indeed frequently the case, and we might add that the eyes are, as a rule, turned to the same side as the head. However, it is important to note that both may change in position during the attack. In the beginning of the tonic stage, the head particularly may be found drawn to one side, while toward the end or in the clonic stage, it may be turned to the opposite side. Furthermore, I have seen quite as many cases in which the head was turned forward, as when it was turned backward or to one side. The eyes need not be turned upward or to one side, but may be found staring forward in a fixed manner giving a very peculiar impression by their complete immobility.

As to the attitude of the limbs, it is seen to vary considerably in different cases. The upper extremities are indeed more frequently flexed than extended at the elbows and wrists, but there are cases in which, especially in the beginning of the tonic stage, either one or both of these joints are extended.

For the lower extremities I found extension of the legs and feet to be by no means the rule, a semiflexed position of thighs and legs being frequently met with.

Another feature worthy of mention is the asymmetry of attitude seen in the majority of cases, *i. e.*, the upper extremity of one side assumes a different attitude from that of the other side and the lower extremity of one side likewise differs in attitude from that of its fellow, so that all sorts of attitudes may be observed.

Moreover, the attitude changes considerably during the attack, particularly during the tonic stage so that the patient passes through all kinds of contortions.

The above mentioned asymmetry of spasm is frequently seen also in the face, although the contractions of the facial muscles may be entirely symmetric.

The hemiplegic cases which so far I have had occasion to observe in epileptic attacks, did not offer any distinct difference in character of the attack from the idiopathic cases. I mean there is nothing in the character of the grouping or distribution that would stamp these cases as organic. There was no preponderance of the convulsions of one side over the other or of one part over the other.

However, I wish to reserve judgment in this regard until I have seen a larger number of cases.

I shall not discuss here cases of partial or Jacksonian epilepsy. These of course conform to other rules.

In many patients the spasms of the various attacks follow the same course or at least begin in the same manner. This is evident by those cases in which the same locality is injured in every attack.

4. *The Condition of Consciousness.*—The determination of the state of consciousness during the epileptic attack is often extremely difficult. When consciousness is preserved to a certain extent, we have 2 means of verifying its presence, *i. e.*, (1) by finding evidences of mental activity during the attack; (2) by evidence of recollection, *i. e.*, by receiving from the patient at a later period, a personal description (of course, not one from hearsay) of events that occur during the attack.

If both of these evidences are absent, we conclude that the patient was unconscious. Frequently we are content with the absence of recollection alone to form this conclusion. However, we must not forget that during the state of muscular contraction of the tonic and clonic stages the patient may be unable to perform any voluntary muscular movements, and, therefore, be unable to give any evidence of mental activity, even if such were present.

On the other hand, we know that many kinds of mental activity are entirely or almost entirely forgotten. I remind you of the dreams of which we frequently have only a hazy recollection, or no recollection at all, except of the fact that the dream occurred. But we need not go so far when we know that epileptics perform complicated acts of which they have no conscious recollection and may never give proof of having any recollection whatever. Therefore, the case is possible in which a patient during an epileptic convulsion might be conscious without being able to give any evidence later of his consciousness during the attack.

I mention these facts in order to call attention to the perplexities by which we are assailed in this regard, and to show how important it is to get *more accurate* evidence of the state of consciousness found at the time of the attack than is implied in such vague statements as "a complete loss of consciousness," or "partial loss of consciousness," "coma," etc., so frequently made.

The manner of obtaining evidence bearing on the existence of some degree of mental activity during the attack is to apply tests of different kinds. For instance, irritation of the skin should be tried and its effects noted. Thus, pricking with a pin, touching with a piece of absorbent cotton, approaching a burning match and watching how the patient reacts toward such stimuli may be tried. Then the special senses should be tested by making different noises, approaching objects toward the eyes, etc., and noting how the patient behaves toward them. For instance, if tickling or stroking the sole produces only a flexion of the toes, dorsal flexion of the foot and some contraction of the thigh muscles, this is an elementary and cutaneous reflex. If the patient withdraws the foot altogether, this shows, at least, a higher type of reflex. If he rubs with his hand the place which was pricked, this shows a slightly higher activity of the central nervous system, and if he turns around and brings his foot in a position where it cannot be well reached, this is evidence of a still more complicated function which must in part, at least, be cerebral.

To illustrate what I have said, I shall subjoin a description of a case as seen in the stertorous stage of an attack. The patient is found lying on his back on the floor, about 15 minutes after cessation of the convulsive stage. His right arm is moderately abducted, the elbow is flexed at a right angle, the wrist nearly so, the fingers semiextended. The left arm is less abducted, the left elbow more flexed (about 60°). The left hand lies across the lower end of thorax, above the epigastrium.

Thighs and knees slightly flexed, and feet in moderate equinus position. Eyes half closed, face has a mask-like expression. All limbs show considerable rigidity, as also jaw and head.

Knee-jerks both decidedly exaggerated; ankle-clonus on both sides, exhaustive at first, but after repeated tests, typical. Pupils react to light, also consensually. Yellowish foam at mouth, respiration deep, although changing in depth as also somewhat in rhythm (19 per minute).

Patient does not brush away flies which assail him, but reacts to painful stimuli, as pricking with pins, if such are repeated in frequent succession, also closes lids when such are lightly touched with absorbent cotton. Closes eyes if such are approached rapidly by examiner's fingers. Also shows conjunctival reflex present, and if the conjunctiva is repeatedly touched, shows signs of increasing consciousness, in as much as the defensive movements become more marked and more varied; but when left alone, he soon relapses again into a condition in which he is entirely unresponsive to the noises made by other patients around him, such as loud voices, rattling, polishing of the floor, etc.

Such a description has more clinical and decidedly more medicolegal value than simply calling the stertorous stage a coma or semicoma, and it is here presented as a plea for more accurate and objective descriptions of the state of consciousness in the different stages of the epileptic seizure.

5. *The Tendon-Reflexes.*—The study of the tendon-reflexes in the epileptic attack has not received very much attention, and the statements found regarding it are rather contradictory.

In the convulsive stage, if the rigidity of the muscles allows a test at all, Oppenheim found the knee-jerks absent. Sternberg saw cases in which they were normal or even exaggerated, and Oppenheim quotes Beevor as finding them more frequently exaggerated than diminished in incomplete or abortive attacks. In my experience they were more frequently exaggerated than diminished, and in 1 or 2 cases there was typical ankle-clonus. In other cases there was an exhaustive ankle-clonus. One case in which the attacks occurred every few minutes, was very instructive. During the attacks the knee-jerks were exaggerated, in the intervals they were normal. In 1 test the tapping of the patellar tendon was repeated several times, until an attack occurred. It was then noted that the knee-jerks all at once became very lively, and at the same moment a new attack set in. I wish to add that the exaggeration of the tendon reflexes found by me was not seen in organic cases only, but in cases unattended by a primary organic brain lesion.

In the postconvulsive stage Church and Peterson, Dana and Binswanger found the knee-jerks diminished or absent. According to Binswanger the knee-jerks give a measure of the severity of the attack, being frequently lost for many hours after a grave seizure. Whether this is really the case, I have not had sufficient experience to state, but wish to record the fact that I found them more frequently increased than diminished, and sometimes attended by spurious or typical ankle-clonus. Hirt also states that exaggeration of the knee-jerks in the postconvulsive stage is quite common.

Typhoid Increasing in Montreal.—Information from Montreal, under date of January 12, says: A hundred or more cases of typhoid fever have developed during the last 3 days. The parish priests of the affected towns are kept busy going from house to house anointing the sick. Warnings have been given from all pulpits and parishioners are urged to boil all drinking water and to take other precautions against the disease. The anxiety of the health officers is increased by the discovery of several cases of smallpox. The present water supply of the municipalities may be shut off and their pipes connected with the Montreal reservoir. It is believed that the present epidemic will finally result in a total abandonment of the St. Lawrence river as a domestic water supply.

SOME REFLEX NEUROSES OF DENTAL ORIGIN.

BY

WILLIAM J. LEDERER, D.D.S.,

of New York City.

Instructor in Oral Surgery at the New York School of Clinical Medicine; former Demonstrator at the New York College of Dentistry.

Reflex neuroses, what a lot of untold suffering this term covers, what a multitude of sins are hidden under this mantle! What does it imply? A nervous disturbance by a cause, other than local. No territory of the human anatomy is more frequently involved than that supplied by the trigeminus; for the fifth is not only the largest of the cranial nerves, it being the sensory nerve of the head and face, and conveying the special sensations of taste, but it is also the nutrient nerve of the teeth and the motor nerve of the muscles of mastication. It gives off the ophthalmic, superior and inferior maxillary divisions, and these subdivide again, and give off branches supplying the eyes, ears, nose, forehead, and scalp, the upper and lower lips, gums, tongue, and teeth. A few ramifications of the maxillary branches arborize again with the ophthalmic division and also with the facial and hypoglossal nerves. The whole is a most wonderful mechanism, constructed most intricately, and a disturbance, no matter how slight, anywhere along its course, may involve any part, or the whole area supplied by its branches.

Dr. F. Savary Pearce, of Philadelphia, in an article on *tic douloureux*, says:

It is stated that the teeth and oral cavity bear to *tic douloureux* the same important relation that the exciting cause does to any general or local affection. There are cases, of course, in which the teeth are not the cause, and there is no etiologic factor resident in the mouth to account for this serious and painful neuralgic affection. But in 50% of the cases of *tic douloureux* there is a very close connection between it and abnormal conditions, such as overcrowding, or more often of pathologic processes, such as pyorrhea and infected pulps.

Dental conditions, such as are liable to act as causative factors of neuralgia, are numerous; they may be classified as:

1. Conditions in which the dental organs causing the malady, indicate a pathologic or abnormal condition, as: Acute or chronic pulpitis; chronic pericementitis (dental periostitis); exposed dentine; caries; abnormal position of teeth (overcrowding); foreign bodies in the pulp cavity; pyorrhea alveolaris (Riggs' disease); foreign bodies in the gums or alveoli; injuries produced by extraction; atrophy of the gums.

2. Those conditions, in which the dental organs causing the malady, do not indicate a pathologic condition, as: Exostosis; impacted teeth; pulp stones.

3. Then we have "neuralgia of the edentulous."

At the first glance it would seem, that a patient suffering from any of the first-named conditions, would apply directly for dental treatment and find ready relief. This is not always the case, as there may be neuralgia of dental origin, without odontalgia and the patient applies for help to his physician. The doctor not having had any dental training does not readily diagnose the dental cause and the patient will not find permanent relief till he finds a physician who has had dental training, or one, who will refer the case to the dental specialist.

The second class of cases sometimes is difficult to recognize and a definite statement can only be made by differential diagnosis, and reflex neuroses caused by these (second-named) conditions will sometimes prove puzzling to even the joint efforts of the physician and dentist.

"Neuralgia of the edentulous" is a condition met in people who have lost their teeth and is probably due to injury of the nerve filament. Gross mentions it in his "System of Surgery," and states, that it is mostly found in old people and is more common in the superior than in the inferior maxillary bone. He ascribes it to com-

pression of minute nerves, distributed through the wasted alveolar process, dependent upon encroachment of osseous matter upon the walls of the canals in which these nerves are enclosed, thus interfering with the transmission of the nervous current. The treatment consists in the removal of the affected part of the alveolar process with sharp-edged bone forceps.

Just as the causes of dental reflex neuroses vary, so unlike are the resulting affections of dental irritation. These can be divided into:¹

1. Conditions producing disturbances of the peripheral organs, namely: (a) The eyes, (b) the ears, (c) those producing muscular disturbances, (d) those producing visceral disturbances, (e) those bringing about trophic and vasomotor changes.

2. Conditions producing disturbances of certain nerves and nerve centers, namely: (a) Facial and other neuralgias, (b) those producing pareses and paralyses, (c) those producing tetanus.

3. Conditions affecting the cerebral centers, namely: (a) Headache, (b) hysteria, (c) epilepsy, (d) chorea, (e) insanity.

In this article I shall quote a number of cases illustrating the first class of conditions, that is, disturbances of peripheral organs. A number of these were recorded by Dr. Brubaker in his treatise on this subject, some I collected from literature on these affections and some occurred in my own experience.

I. OCULAR DISTURBANCES.

Hutchinson in the Ophthalmic Hospital Reports says:

Whether as ophthalmic surgeons we may incline to admit or deny the connection between dental irritation and amaurosis, we must certainly grant that very curious facts are extant and quite sufficient to make the removal of all possible sources of annoyances to the fifth nerve a precaution, well worth adoption. At any rate I can speak from my own experience most strongly as to the advantage often obtained from attention to these parts.

In many cases of so-called strumous ophthalmia in young children, in which small ulcers on the surface of the cornea or near the edge are attended by intolerance of light, lacrimation and pain, the use of the gum lancet at once relieves the more urgent symptoms. In the case of adults it is surely the duty of our profession to take every opportunity of spreading information as to the possible ill consequences of retaining stumps in the jaws.

Looking at the matter from a wide field of view and remembering the frequent production of cancer of the tongue, cheek, and gums by broken teeth, and how decayed stumps often become the cause of neuralgia of the most obstinate character, we shall become yet more deeply impressed with the importance of the recommendation. In many instances in which the fifth nerve is rendered irritable by a carious stump, the patient is not aware that the stump is the seat of pain. Of this a good example came under my notice a few months ago.

Neuralgia of the eyeball cured by tooth extraction. Mrs. H., aged 28, a woman somewhat enfeebled by nursing, came to me from Moorsfield, stating she could not use her left eye. She had suffered pain for one month in the forehead. The pain was severe, but not constant, and neuralgic in character. The eye was watery and irritable, intolerant to light and she could only read large capital letters. On account of the intolerance of light, I could not test her vision. I concluded to examine her mouth, so as to be able to preclude any irritation of the fifth nerve and found a carious molar, which I had extracted, although she did not complain of toothache. With the removal of the tooth the pain in the eye vanished.

Fruehauff² reports the following case:

A young lady had partially lost her vision in the left eye. She came to him for dental treatment and he had occasion to extract 8 roots for her. After these were removed her eyesight was restored, showing the trouble was due to irritation of the trigeminus.

Dr. Edward T. Ely³ reports the following case:

Paresis of orbicularis palpebrarum; irregular spasms of ciliary muscle; monocular diplopia. The patient, a male of 26, complained that vision of the right eye had suddenly become blurred and that he saw double with that eye. There was no pain or redness. Pupil was small and movable and fundus normal. He has paresis of right orbicularis. Lids cannot be closed completely and the eye is watery. V = $\frac{2}{20}$ and with $\times \frac{3}{8}$ c. 180 = $\frac{2}{20}$. A careful examination of the teeth showed nothing abnormal. The patient was ordered to take some mercury and potassium iodid, which he did for some time without benefit. One night he was seized with severe pain in one of his upper

molar teeth. The next day the tooth was extracted, and an abscess which had formed about its roots was evacuated. The paresis of the orbicularis muscle immediately disappeared, and V became $\frac{2}{3}$ without glass. There was no doubt as to the astigmatism in this case, as vision was subjected to the most careful tests.

H. M. Gill, M.D., reports a case of Garretson's:

Amaurosis caused by overcrowded teeth in a boy of 11, whose sight was perfect, till one morning he found he could not see. He was brought to Charing Cross. On examination it was found that his arch was in a crowded, corroded condition, and 2 permanent and 4 temporary teeth were extracted. As soon as the teeth were removed, he could distinguish light from darkness. After 11 days he was discharged cured.

Clarence A. Vesey, in his work on "Diseases of the Eye," says:

Reflex amblyopia is occasionally met; the most frequent cause probably being irritation of the fifth nerve by some defect of a tooth. The condition disappears with the removal of the cause.

II. AURAL DISTURBANCES.

Loder⁴ reports the following case:

A child had suffered for some time with earache. The cause was not apparent until the mouth was examined. A fragment of enamel was discovered, which had been left behind from one of the deciduous teeth. This was wedged in the gum alongside of a newly erupted molar. The membrana tympani was decidedly inflamed. The removal of the fragment cured the neuralgia and the membrana tympani returned to its natural appearance.

Sexton,⁵ in 1,500 recorded cases of aural disease, found that a third owed their origin or continuance to diseased teeth.

Abbott,⁶ at a meeting of the New York Odontological Society, related the following case:

A lady had been under the treatment of an excellent aurist for inflammation and pain in the ear, but without being benefited. At the same time she was suffering from pain in a right lower molar, which had been filled some 15 months before. I found the pulp dying, and opened the pulp chamber. At the moment it was perforated, the pain in her ear, which was at that time quite severe, left her, and in a few days the ear was perfectly well. It has given her no trouble since.

Dr. Roosa⁷ relates the following interesting case:

Patient, aged 40, had deafness, tinnitus, and itching in the left ear for 2 years, and had had neuralgia of the jaw, face, shoulder and arm of the left side for some time; dizziness and nausea for some time; had had considerable neuralgia before and is subject to headaches. Hearing distance of the right ear $\frac{1}{2}$, left ear $\frac{1}{4}$; tuning fork heard on vertex, but in left ear. Bone conduction better than on aerial on each side. Patient has a hard swelling high upon the gums above the last molar tooth of left side. She had an ulcerated tooth there with similar swelling, requiring lancing further forward. Present swelling increasing in size, but not tender. Right membrana tympani opaque, fair light spot, fair position. Left membrana tympani fair light spot, fair position. The diagnosis here, is neuralgia and trophic changes in tympanum from irritation of the fifth nerve.

III. MUSCULAR DISTURBANCES.

Spasms of the facial muscles are due to irritation of the facial nerve, and may be clonic and tonic in character. They are, as a rule, confined to one side of the face, but may be bilateral. The irritation causing them may be central, but the anatomic relationship between the trigeminus and portio dura, shows that facial spasms can be brought about by dental irritation.

Dr. C. N. Pierce⁸ reported the following case:

A child of 14 was suddenly seized with marked contractions of the superficial muscles of the right side of the face, giving it a peculiar distorted appearance. Although the contraction was continuous, there was from time to time the twitching of individual muscles. No apparent cause being present for the trouble, the mouth was carefully examined. It was found that the inferior second molar of the right side had not erupted, owing to an indurated condition of the gum covering it. After liberation of the crown by excising the indurated tissue, the muscular spasms soon subsided and entirely disappeared.

Trismus, or the tonic contraction of the masseter muscle is caused by irritation of the motor root of the trigeminus. The irritation mostly arises from the irregular eruption of the wisdom teeth. The affection is

mostly tonic in character, though the clonic form has been observed. I had occasion to see a number of these cases in dispensary practice, and relief was always obtained after the extraction of the erupting teeth.

Torticollis or wry-neck may also be the result of dental irritation, as the following report of Dr. Hancock⁹ illustrates:

A young woman was brought to me at the Charing Cross Hospital with wry-neck, the head being drawn nearly to the right shoulder, accompanied by considerable pain. She had suffered in this way for about 6 months, and had been treated by blisters to the spine, leeches, various liniments, and internally with quinin, calomel, iron, valerian, etc., but without benefit. She was otherwise in good health and I concluded the mischief depended upon some local cause. An examination of the spine showed that there was no lesion in that situation, but upon looking into the mouth a stump and a partially decayed tooth were seen in the lower jaw on the left side. When I decided to have these extracted, she assured me that they caused her no inconvenience. Nevertheless she was induced to have the operation performed, and she got well in a few days.

IV. VISCERAL DISTURBANCES.

To attribute visceral disturbances to dental irritation may seem a little far fetched, but if one considers the anatomic relation of the trigeminus and the sympathetic nervous system, the possibility of such reflex action will become apparent. The accompanying diagram illustrates the relation of the superior maxillary division of the fifth nerve and the sympathetic cervical ganglions.

The intimate relation¹⁰ which the trigeminus bears with the points of origin of the sixth, seventh, eighth, ninth, tenth, eleventh, and twelfth cranial nerves in the floor of the fourth ventricle possibly explain some of the phenomena which are considered as reflex in character and whose starting seems to depend upon some irritation of the fifth nerve by means of various branches. "The trigeminus communicates with the facial nerve through the various sympathetic ganglions, and the facial nerve gives branches to the auditory and glossopharyngeal nerves, and through its auricular branch communicates with the pneumogastric nerve. The pneumogastric supplies the pharynx, esophagus, stomach, alimentary canal, the larynx, trachea, heart, and bloodvessels, and is intimately connected with the digestive, respiratory, and circulatory apparatus.

Thus we have a reflex arc extending from the oral cavity into the pelvis, and it becomes plausible that a peripheral irritation, as a defective tooth, can produce a distal response, as uterine contractions. The systemic derangements of infants during the teething period are too well known to go into detail, but they furnish an excellent example of reflex conditions due to dental irritation.

Dr. G. V. Black,¹¹ of Chicago, reports a case of gastric neuralgia due to dental irritation:

A physician once brought a patient with persistent neuralgia of the stomach to consult me. Inquiry developed the fact that in the beginning of the trouble there had been much pain

A, vidian nerve; B, superior maxillary nerve; C, sphenopalatine ganglion; D, carotid plexus; E, first cervical nerve; F, upper cervical ganglion; G, eighth cervical nerve; H, middle cervical ganglion; I, lower cervical ganglion; J, first thoracic nerve. (Diagram from Eckley after Testut.)

about the jaws and the ear of the left side. The patient was nearly 70 years old, and many teeth were missing. Pain was often very severe shortly after eating, and things hot or cold could not be taken without increasing pain. A patient exploration finally disclosed a large absorption of the root of a lower third molar near the gingival line that extended into the pulp chamber. This was found while carefully exploring the attachments of the periodontal membrane to the neck of the tooth. Removal of the tooth relieved the neuralgia.

Dr. Pointes¹² records the following case:

A patient, after an attack of toothache, suddenly lost his voice. The aphonia was followed by anorexia, cough, wasting, and feverishness, which led to the belief that he was suffering from laryngeal tuberculosis. But the lungs were sound and there was no tenderness over the larynx. There was slight inflammation of the pharynx; all the molars in the left under jaw were decayed and the gums and periosteum around them swelled. The teeth were removed, the gums cauterized and gargles employed. On the day the teeth were extracted the suffocative spasms which had troubled the patient abated, and on the following days the other symptoms quickly disappeared.

Cardiac palpitation due to dental irritation.—Remak¹³ relates a case of cardiac neurosis as a result of an erupting wisdom tooth:

The patient, a young woman of 21, complained of cardiac palpitation, preceded by pain in the molar region. The symptoms became aggravated, mental distress, a feeling of suffocation, and finally trismus developed. The trismus was reduced by means of the galvanic current, the tooth extracted, and shortly after the cardiac symptoms disappeared.

Dr. Hullihan¹⁴ reports a case of vicarious menstruation due to dental irritation.

V. TROPHONEUROSES.

Trophoneuroses are divided into diseases of peripheral, spinal, or cerebral origin, according as the peripheral nerves, the spinal cord, or the brain are the seat of the lesion.

After traumatic lesions of the peripheral nerves circumscribed cutaneous red patches are often observed on the extremities resembling chilblains, sometimes associated with pseudophlegmonous swelling of the subcutaneous cellular tissue. (Hamilton.) Transitory and recurring patches of erythema, which, no doubt, are of nervous origin, have been observed on the forehead and the root of the nose in connection with trigeminal neuralgia, and occasionally on the hand in brachial neuralgia.

Trophic Disorders of the Hair.—Ross, in his "Diseases of the Nervous System," says: "The hair frequently suffers from nutritive disorders, subsequent to lesions of the nervous system. Such disorders often occur after experimental injuries of nerve trunks in animals. After section of the infraorbital nerve in rabbits the long hair of the beard falls out, while chemic irritation of the sciatic nerve in the same animal is followed by ascending neuritis, and myelitis is frequently associated with loss of the hair on the posterior part of the body." (Eulenberg.)

The hair over the region of distribution of a nerve affected with neuralgia has sometimes been observed to become hypertrophic and even increased in number, but as a rule the effect of neuralgia on the hair is to make it brittle and cause it to fall out in considerable quantities.

Localized greyness of the hair often assumes an intermittent character, increasing during, and for some time after, an acute attack of pain, while a partial or total restoration of color takes place in the interval between the paroxysms. (Anstie.)

Milian,¹⁵ at a seance of the Société Française de Dermatologie et de Syphiligraphie, reported a case of alopecia areata:

A man aged 35, who had suffered much from carious teeth, of which he had a great number, presented a patch of alopecia areata in the mustache over the right upper lateral incisor. This tooth after a severe neuralgia of both jaws had remained very sensitive, and the patches of alopecia had developed over it, and at the same time vesicles identical in appearance with those of herpes had appeared on the corresponding part of the gum.

The hairs about the border of the patch were easily extracted and presented the usual appearances observed in this disease. The skin was thinned and presented a marked anesthesia. There were no other patches of alopecia. The patient was directed to have the mouth cleansed and the teeth looked after by a dentist, and was given quinin internally in moderate doses. Shortly after the jaws had been put in good condition, the sensitive incisor having been extracted, the alopecia ceased to extend. Later the neuralgia ceased, the sensibility of the skin returned, and at the end of 4 months the plaque was completely covered with hair.¹⁶

Garavaza¹⁷ reports 4 cases, in which appeared a bald spot at a point corresponding to the position of a carious tooth. The alopecia had been preceded by severe neuralgic pain in the face; but after extraction of the tooth, the alopecia entirely subsided, and after a short while the bald spot became covered with a healthy growth of hair.¹⁸

In my own practice I saw a case of herpes of the gum and face, with a condition of periostitis, affecting several teeth of the right lower jaw. The condition was caused by an erupting wisdom tooth, and after it was entirely through, the cutaneous affection and periostitis quickly disappeared.

Hilton, in his lectures on "Rest and Pain," mentions a number of cases of "furred tongue on one side," associated with carious teeth, which condition quickly disappeared as soon as the teeth were extracted.

Trophoneuroses of the Salivary Glands.—Secretory disturbances of the salivary glands may occur in connection with lesions of the peripheral fibers of the trigeminal or the facial nerve or the cervical sympathetic. In trigeminal neuralgia an increased secretion of saliva is not infrequently due to reflex irritation conveyed through the lingual nerve of the fifth as the afferent, and the chordæ tympani as the efferent channel. Stimulation of the glossopharyngeal is even more effectual in increasing the flow of saliva than of the lingual nerve.

This also accounts for the increased salivation so frequently met in patients who have excessive deposits of salivary calculus; the gums through mechanical irritation (by the calculus) and vasomotor changes become hypertrophied and hyperemic.

In presenting these few cases I trust I will not create the impression that it is my belief that "all the ills that human flesh is heir to" can be traced to dental irritation, or can be treated as such. I simply wish to point out the important relation of the dental organs by way of the trigeminal to other parts, that irritation of the dental branches may exist without odontalgia, and that the result of the irritation may be reflected distally, and therefore the importance of a careful oral examination of patients suffering from neuroses whose etiology is doubtful.

Modest Needs of the Chicago University.—The New York Sun says: If President Harper's plans for the development of the University of Chicago are to be realized, new gifts amounting to nearly \$20,000,000 must come to the University. President Harper outlines his plans in his decennial report. A list of the gifts needed follows: New endowment to make up the present deficit in current expenses, \$6,000,000; for new buildings, \$3,200,000; for the erection and equipment of 5 hospitals, \$5,000,000; for Rush Medical College, \$1,350,000; endowment of scholarships, professorships, etc., \$4,000,000. Total, \$19,550,000.

INTRAUTERINE FLUSHING AND DRAINAGE FOR INFECTION: THE PASSING OF THE CURET AND DOUCHE.*

BY

HORACE G. WETHERILL, M.D.,

of Denver, Colo.

Professor of Gynecology, Denver and Gross College of Medicine; Surgeon in Charge, Denver Woman's Hospital, etc.

With the noteworthy, and perhaps the single exception of the gonococcus infection, which may be engrafted upon the healthy and unbroken mucous membrane, infectious diseases of the female genital and pelvic organs are to all intents and purposes nothing more nor less than wound infections. They are of the same origin, and their course and consequences are similar to like pathologic processes elsewhere in the body, and they are subject to the same laws for prevention and treatment. The anatomic structures, the secretions, and the relations of parts peculiar to this region do, however, exercise an influence over the growth and development of these infections, and to some degree they determine the direction and severity of the malady and its complications or sequels. This is exemplified by the wellknown bactericidal power of the vaginal secretion on the one hand, and the peculiarly favorable conditions for the extension of established infections through the lymphatics, veins, or peritoneum on the other. However, these local peculiarities play no important part in the modification of the rules for prevention or treatment, as the knowledge of the resisting power on the part of the vaginal secretion is no justification for lax methods in one's technic, nor does the particular anatomic arrangement justify or make necessary radical differences in treatment from that indicated in like infections in other parts of the body.

The broad general principles for the prevention and treatment of wound infections are well worked out and established, so far as is possible with our present knowledge of the sciences of bacteriology and surgery, and may be briefly summed up as follows: Prevention depends upon the *practical* sterility of the field and environment about the wound and of all things that come in contact with it—that is, hands, instruments, sponges sutures, dressings, etc. Treatment is directed (1) toward the localization of the infection through evacuation of pent-up secretions, and the relief of tension, and consequent diffusion from absorption, which implies physiologic rest and drainage; (2) toward the elimination of toxins and poisons already absorbed; and (3) toward the support of the patient in her battle with the disease.

In regard to prevention, the qualifying word "practical" is used advisedly, as it is well known that actual sterility is impossible of attainment for the skin of the surgeon and patient, though it is for the instruments and dressings, but it is also well known that from a practical standpoint the skin may be made so clean that infections do not occur, either through the attenuation of the virus, or its dilution to a point where it may be taken care of by the tissues, some of which have great power in this regard, particularly the peritoneum. In this connection, permit me to say that our former faith in certain poisonous chemic antiseptics is waning, and there is a growing disposition to depend more and more upon mechanical means (soap and hot water and a good brush vigorously used) and less upon the delusive dip of the half-washed hands into the 1-1,000 solution of mercuric chlorid, the inefficiency of which is proved for this purpose as well as for the vaginal irrigations hereafter to be referred to.

Applied to infections of the female genitals, the general surgical principles here referred to, simplify and facilitate the prevention and treatment of such con-

ditions and yield far better results than the routine treatment with the curet and mercuric chlorid douche, so long in vogue and still so tenaciously adhered to by many practitioners.

In maintaining that the curet and mercuric chlorid douche should not be used in *acute* infections of the female genital organs, I take the ground that they are unnecessary and universally injurious. That patients suffering from such conditions have been cured and have recovered in the hands of many of us, must in the light of the facts now before us, lead to the conclusion that they have recovered in spite of the treatment rather than because of it.

Please bear in mind that I am speaking of acute infections. Nothing in this paper is intended to apply to chronic endometritis, the result of old infection; nor to those cases of sapremia, after delivery at term, or of abortion, in which the symptoms are clearly due to the retention of putrid products of conception, which must and should be instantly removed, with the dull curet, if necessary. The differentiation of these conditions must be made and in almost every instance can be made by making a very careful study of the history and symptoms of the case, but if there be a doubt after a digital examination has told all that is to be known in regard to the condition of the inside of the uterus, and there be the least evidence of acute infection or of diffusion of the disease beyond that organ, the curet and douche should be discarded instantly, as they can serve no good purpose, there being no foreign body to be removed. Furthermore, they do great harm through the distribution of the infective process and dissemination by breaking down the natural barriers and promoting the extension of the disease.

Please allow me to quote some eminent authorities in regard to this question, for while there is a very general agreement in regard to it among the leading gynecologists and obstetricians of this country, there is still a vast deal of uncertainty in the minds of many others which should be cleared away at once in the interest of our patients, as well as of modern medical science.

First, as to the primary sterility of the vagina and the effect of the antiseptic douche upon infective bacteria when once introduced. Williams¹ says in his excellent new book upon obstetrics:

As a result, therefore, of the work of Krönig and Menge and myself, it has been fairly satisfactorily demonstrated that under normal conditions pyogenic cocci are never present in the vagina of pregnant women, and that therefore there is no possibility of autoinfection as far as these organisms are concerned, and whenever they are demonstrated in the uterine secretion of puerperal women, they should be regarded as affording conclusive evidence of external infection.

An interesting fact in connection with the question of autoinfection is, that those who believe most firmly in its possibility, and who are in the habit of employing prophylactic vaginal douches for the destruction of the organisms in the vagina, have thus far been able to present far less favorable statistics than their opponents. Thus, Ahlfeld finds that 38% of his patients have a rise of temperature during the puerperium, even after the use of the prophylactic douche. Again, Kaltenbach, while chief of the Lying-in Clinic at Halle, always resorted to its routine employment, but the statistics show a very material improvement since his successor, Fehling, discontinued the practice. Furthermore, the results of Leopold and Mermann, who do not use the douche at all, show a constant improvement corresponding with the increasing precision with which objective asepsis is carried out.

S. Mark,² in an excellent paper on the "Bacteriology of the Puerperal Uterus," etc., says:

It has been proved beyond the shadow of a doubt that neither *Staphylococcus albus* and *Staphylococcus aureus*, nor *Streptococcus pyogenes*, nor *B. coli communis* are to be found in the healthy vaginal secretion of the pregnant woman.

Regarding the curet and antiseptic douche in puerperal infection, Williams³ says:

Curetage as a routine measure in all cases of puerperal endometritis is by no means to be recommended, for the reason that in the most severe cases there is usually absolutely nothing in the uterine cavity which can be removed, and its employ-

* Read at the meeting of the Colorado State Medical Society October 8, 1903.

ment can only do harm by breaking down the leukocytic wall, which serves to prevent the invasion of the deeper layers of the uterus by the offending bacteria. On the other hand, when the uterus contains more debris, its removal is more readily effected by means of the finger than by the curet.

The routine use of mercuric chlorid or carbolic intrauterine douches in the treatment of these cases is counterindicated on several grounds. In the cases due to virulent streptococci a histologic examination shows that the organisms have penetrated deep down into the tissues by the time the initial chill and rise of temperature occur. Under these circumstances the employment of an antiseptic douche is not rational, inasmuch as the germicidal fluid cannot possibly penetrate the uterine wall sufficiently deep to reach the bacteria, which are giving rise to the symptoms, and upon which the further spread of the disease is dependent.

Moreover, it has been shown experimentally by Bumm that mercuric chlorid injections penetrate the tissues only to a very slight extent. He took the liver of an animal dead of anthrax, and after soaking it for 30 minutes in a 1-1,000 mercuric chlorid solution, placed it upon a freezing microtome, and cut thick sections from it. After cutting off about .1 mm., he inoculated the next section into another animal which succumbed to anthrax, thus showing that the germicidal action of mercuric chlorid had been exerted only upon the surface. If this be the case in the laboratory after the tissues have been immersed in the antiseptic solution, what effect can we expect upon organisms embedded in the muscular wall of the uterus from the transitory application to the surface of a few liters of a weak mercuric chlorid solution? Bumm likewise showed that the streptococci made their way through the uterus with great rapidity, traveling 2 cm. or more in the space of 6 hours. What has been said concerning mercuric chlorid applies equally well to the other disinfectants.

On the other hand, their employment in cases of putrid endometritis is even less rational. In the vast majority of such cases, simply cleaning out the uterus with the finger or curet, followed by a douche of sterile salt solution will lead to a rapid fall of temperature and the amelioration of untoward symptoms. The object of giving a douche is simply to wash away the debris which has been left behind by the finger, and for this purpose, sterile water or salt solution is far better than any antiseptic solution.

In addition to these somewhat theoretic objections, there is a very practical one: That the employment of antiseptics may do an immense amount of harm. Not a few cases of sudden collapse following the use of carbolic acid douches are on record, while, in some instances, intrauterine injections of mercuric chlorid have been proved to have been the direct cause of death.

H. J. Boldt, in a paper on "The Surgical Treatment of Puerperal Infection," says:

The indiscriminate cureting which, unfortunately, is still being done to a large extent in puerperal women who happen to have an elevation of temperature, or who may perhaps have a slight chill, cannot be too severely condemned. I have seen a number of deaths which, in my opinion, were indirectly due to that procedure. Another, although a minor intervention compared to curetage, resorted to much oftener than necessary, is repeated intrauterine irrigation. The chills which the patients often have after such intervention, may usually be ascribed to it.

At the last meeting of the American Gynecological Society, a paper by Dr. H. N. Vineberg⁵ was read, in which he said:

Curetage is indicated when there are evidences of placental residue in the uterus, independent of the variety of bacteria that might be found in the uterine cavity. In those rare cases in which adherent and sloughing placental tissue can not be removed either with the sharp curet or fingers, hysterectomy is indicated, providing the patient is not already moribund.

This statement was almost unanimously taken exception to by those who participated in the discussion, some of the opinions given being as follow:

Dr. William R. Pryor: Relative to the use of the curet in a case of local infection, to inflict trauma over the whole inside of the uterus with this instrument, usually means the dissemination of the infection, and he believes it is bad practice.

He condemns hysterectomy unqualifiedly in patients suffering from septicemia, saying that nothing can be gained by the removal of the uterus.

Dr. J. Whitridge Williams: If a woman has streptococcal infection, the curet is harmful, and he believes the bad results of many practitioners are due altogether to the practice of cureting in such cases. Whenever he sees a woman with streptococcus infection, he does not think of using the curet, but simply gives her a single douche of sterile salt solution, and leaves her alone. On the other hand, if he finds the uterus contains necrotic

material, particularly if the infection is due to putrefactive organisms, he cleans out the uterus with his finger. Even then he does not curet.

Dr. Edward P. Davis: He repeated the dictum of Leopold, that the surgical treatment of puerperal sepsis at present should be conducted on the one principle of the evacuation of pus or the drainage of abscess, and that hysterectomy is only indicated in those cases in which the adherent placenta can be removed by no other method.

Dr. Malcolm McLean: Curetage has become a uniform method of treatment in the hands of the average obstetrician, and even the sharp curet is used in many cases, the consequence being that the mortality has been increased enormously in septic cases. Emptying the uterus is an absolute necessity, especially when there is evidence of putrid absorption, attended with chill and high temperature. The endometrium should be left alone as much as possible. The intrauterine irrigation tube has its place in washing out the detritus, but he questions the propriety or safety of repeating these washings frequently. He recommends the use of iodine water for douching.

Dr. Henry D. Fry: If the streptococci infect the musculature of the uterus, one cannot possibly reach the infection with the curet, but in the majority of cases of streptococcus infection the area is localized. It is not general. Nature attempts to protect the patient by throwing out a protective zone of inflammatory tissue, in which there are a number of leukocytes and the streptococci are kept out. If the curet is used, this protective zone is broken down, so that the streptococci are enabled to gain entrance to the system and cause a general systemic infection. In cases of criminal abortion, he has repeatedly seen patients with septic conditions doing fairly well, yet after the use of the curet some of the patients died in the course of a few days.

Dr. Seth C. Gordon: Every time an abrasion is made in the uterus with the curet or knife, in the vagina or anywhere else, unless the operator goes straight to the point of infection, he opens up a new avenue of infection. He thinks the use of the curet ought to be largely out of date.

In his new book, just from the press, "The Practice of Obstetrics," Dr. J. Clifton Edgar says:

The endometrium should never be cureted in streptococcal infection; in the first place 80% of these patients recover spontaneously from the formation of a protective layer of leukocytes in the decidua lining of the uterus. The germs leave the uterus in connection with the necrosis and expulsion of the decidua; the use of the curet is therefore distinctly meddling. It breaks down the defensive wall and allows the streptococci to penetrate into the uterus and gain the peritoneum; this being the method by which curetage may set up peritonitis.

That the use of the curet is irrational in these acute infections, which are mostly of the streptococcus, staphylococcus, or colon bacillus varieties, is bound to be conceded if we agree that there is very often no putrid foreign body to be removed from the uterine cavity and that even if there were, it would be unwise to break down the natural barriers to the extension of the infective process with the curet, when the indications of the case can be better met by other means.

The intrauterine and vaginal douche of mercuric chlorid is also now generally believed to be without other good effect than the mechanical one of washing away the accumulated discharges, a function which is better met by the douche of plain water or of salt solution. On the other hand, it has been definitely shown that the douche of mercuric chlorid solution as a preventive measure and as well as a therapeutic one, is a potent factor for harm in that it reduces the natural resistance of the vaginal secretion to infection, washes away the natural lubricant of the genital canal, thus predisposing the obstetric patient to lacerations that might not otherwise occur, and further complicates the case with the danger of mercurial poisoning. In addition to all of this, the disturbance of the parts incident to the giving of an intrauterine douche for an infection almost always results in the diffusion of the disease as is evidenced by a material rise of temperature afterward.

The conclusion seems to be forced upon us that in the presence of an acute infection of the genital tract of women, incident to either labor at term or to abortion (complete or incomplete) the indications are to remove putrescible material, when present, with as little disturbance of the tissues as may be possible; to provide perfect drainage and a means for maintaining it without

disturbing the patient or the parts involved, to secure absolute rest, promote elimination and sustain the general strength of the patient and fortify her in her battle with the disease in all possible ways.

Briefly stated, the indications are to treat infection of the female genital organs just as the modern, up-to-date surgeon should treat like infections elsewhere in the body, the cardinal principles being absolute rest and quiet of both the patient and the part involved, drainage and evacuation of septic foci, soothing and cleansing applications to the parts, promotion of elimination and support of the patient.

Conceding then that the uterine curet and antiseptic douche are at last to be set aside by the rational scientific practitioner of our profession, what have we offered to take their place, for in my judgment the passing of these vicious devices for the treatment of genital sepsis depends upon the substitution of some other plan of treatment which appeals to us as being practicable, and can be shown to produce superior results. The curet and douche habit is so entrenched in our minds and so much a part of our routine practice that it will not be abandoned upon the simple *ipse dixit* of a few bacteriologic, gynecologic and obstetric experts who have demonstrated to their own satisfaction that it is dangerous and should be stopped, because forsooth they give us nothing to take

THE TUBE.

1. Cut two holes in a long piece of drainage tubing as indicated at A and B. 2. Draw one end of the tube through A and out at B, thus inverting that portion of the tube between the holes as seen in 2. 3. Bend the legs of the tube down so that the holes A and B will be left open for drainage. If bent in one direction they are open, if in the other closed. Tack with a blind stitch at C.

its place, and the practitioner of this day is nothing if not aggressive, active, and too often meddlesome through his desire to be up and doing. So it is of vital importance to direct his energy along safe therapeutic ways in order to keep him out of the old rut.

The plan I propose for the treatment of these infections meets all the requirements stated and conforms to these general surgical principles accepted everywhere as being the best for such infections in other parts of the body; furthermore, it has been tried sufficiently and in the hands of enough men of skill and ability to have established for itself a record of good results unattainable by any other plan.

The plan I propose and use comprehends the removal of putrescible debris from the uterus by the finger and blunt placenta forceps, followed, if necessary, by flushing with salt solution, potassium permanganate solution or diluted alcohol, all nontoxic and used only for their mechanical effect in washing out loose fragments; then my double drainage tube is gently inserted to the uterine fundus and flushed with salt solution or diluted alcohol to assure its freedom from obstruction by clots or debris, the vagina is lightly packed with iodoform gauze, and the patient is returned to her bed if she has been removed, for no anesthetic is given and the manipulation is so gently

done that none is needed. The tubes are then flushed every 2 to 4 hours with alcohol of a strength varying from 25% to 95%, according to the severity of the symptoms and the degree of smarting it produces at the vaginal outlet. This is a modification of the alcohol method of Carossa, but in my judgment and experience a very important and valuable change has been made in leaving all packing out of the uterine cavity and in the use of double tubes for flushing and drainage without disturbing the patient from her position in the bed.

Socalled drainage with gauze is no drainage at all in the proper acceptance of the term and though it does carry off a limited amount of thin fluid or blood serum it acts as a perfect dam for pus and the broken down particles resulting from suppuration and sloughing while the flushing tube to which I refer carries them off at frequent intervals and keeps the cavity free from that distention and pressure that is so great a factor in promoting absorption. The moment the tension is relieved from an abscess cavity the septic absorption is apt to be arrested and the fever subsides and the same principle obtains in this very case, for how often do we find a tight internal os damming back an ounce or more of filthy, foul-smelling debris.

Furthermore, the diluted alcohol used for flushing the tubes meets other indispensable indications in the treatment of such patients, for beside the mechanic effect of removing debris, it has the virtue of a chemic action in arresting putrefaction and bacterial growth, the same as when the tissue is placed in a bottle containing the alcohol, the uterus in this instance being the bottle in which the alcohol is so frequently poured. It is nontoxic and its supporting and stimulating effect through being taken up by the absorbents is no insignificant factor.

Best of all, however, is the fact that it can be employed by every capable practitioner everywhere and that its use involves no surgical operation, no anesthetic, no frequent and painful handling of the patient; and that it will yield results heretofore unattainable by any other method.

In a paper read before the El Paso County Medical Society last February and published in the *American Journal of Obstetrics*, Vol. xlvii, No. 5, 1903, the details of my method are given with some reference to results and a typical temperature chart, it having for a basis the Carosso alcohol irrigations but with the vital difference that the tubes are used double and without the gauze packing, which are details I find absolutely necessary for the attainment of the best results.

At the Woman's Hospital in Denver the method is the routine treatment for all intrauterine infections after abortion, complete or incomplete, or labor at term, and there we get not a few of both of these varieties from the outside in various stages of progress and so long as there is no great diffusion of the disease beyond the genital organs themselves and no metastatic septic foci in the lungs or elsewhere, the patients are found to make rapid and complete recoveries and even in some instances when the disease had been broadly disseminated and septic pneumonia established the recovery was complete and satisfactory though somewhat tedious.

I have been so impressed with the great dangers of the prevailing practice in the treatment of acute genital infections with the indiscriminate application of the curet and mercuric chlorid douche, with the utter inadequacy of other wellknown measures and our helplessness in the face of one of the most common and dreadful diseases known to us, and last of all, with the safety, simplicity, and security of the method here advocated, that a vigorous presentation of the subject has seemed to me fully warranted and justified.

SPECIAL ARTICLES

THE RELATIONSHIP EXISTING BETWEEN THE OPHTHALMOLOGIST, OTOLOGIST, AND THE GENERAL HOSPITAL.¹

BY

FRANK ALLPORT, M.D.,
of Chicago.

Clinical Professor of Ophthalmology and Otology, Northwestern University Medical School, etc.

The great majority of ophthalmologists and otologists are compelled to do most of their operative, and especially their *private* operative work, in a general hospital. They are, therefore, brought into almost daily contact with the problem as to how the general hospital can be best adapted for their peculiar needs, and it is with the purpose of relating some personal experiences in general hospital work, and with the hope of eliciting some useful and pregnant discussion, both special and general, upon this interesting and important subject, that this article is written. There are in this country a few private or semiprivate hospitals for the care of paying patients suffering from eye or ear diseases; such as Knapp's in New York, or Holmes' in Cincinnati, where the surroundings are such as to place this class of patients under almost ideal conditions for the attainment of the best possible results. There are also public infirmaries, such as the Illinois Eye and Ear Infirmary, or the Massachusetts Eye and Ear Infirmary, etc., for the treatment and care of charity patients, where little is left to be desired for the performance of the most scientific work. But the unfortunate rich man who is compelled to submit to a cataract or mastoid operation, must, as a rule, either be operated on at his own home or in a general hospital, neither of which is adapted for obtaining the best results. This is lamentable, not only for the man of means, who is willing and able to pay for the best of everything, but also for the surgeon who is, of course, especially anxious for good results with patients of this class, as his living depends upon them, and the outcome is most important in the establishment of a reputation for faithfulness and skill. It thus transpires that the man who pays nothing, is often treated in a special hospital, built, equipped and managed for the care of eye and ear patients, with the best operating-rooms, best instruments and devices, best regulation of illumination, best nurses, isolation wards, etc., while the man who pays, must, perhaps, take his chances in a general hospital, improperly regulated as to light, with no isolation ward, no proper equipments nor instruments, no properly trained internes nor nurses, comparatively little indeed to protect him from infection and other misfortunes, and in short, but little that an honest surgeon can honestly recommend and with much that he must wish to conceal and condemn. I well remember two patients upon whom I operated for cataract in one day. The operations were both perfectly smooth and uneventful, and the patients were given adjoining beds in the women's surgical ward of a general hospital. Upon the third day the bandages were removed and the eyes presented an ideal appearance. The eyes were carefully washed, some atropin instilled, and the bandages reapplied. Within 36 hours the bandages were removed and a virulent streptococcus infection was in active operation. Both eyes were rapidly lost from purulent panophthalmitis, and removed. I must have infected these eyes at the first dressing, but how? My hands were thoroughly scrubbed and disinfected before the dressings were made and between dressing the two patients. I shall always feel that the infection proceeded from the dressing tray or its contents, and as the ward nurse was handling all kinds of surgical cases, and the tray and its contents were left exposed to the more or less germ-laden atmosphere of a general surgical ward dressing-room, and were more or less handled by various nurses, internes, attendants, etc., such a conclusion seems not only possible, but highly probable. An ophthalmologic colleague in the same hospital, at about the same time, suffered similar results in 2 private patients in private rooms, and the 4 cases made us feel

exceedingly uncomfortable for a long time, owing to various menacing threats of malpractice proceedings, which happily after a time subsided. The incident, however, was not without its lesson, for with these unhappy cases as a text upon which to base a sermon, my colleague and I have reorganized the eye and ear service of this hospital, so that at the present time it is, while very far from being perfect, in very fair running condition, and we at least feel a measurable sense of security that our patients will not be subjected to the frightful results just enumerated, than which nothing could be much worse.

Perhaps one of the most important moves toward the establishment of a satisfactory eye and ear service in a general hospital is the appointment of a special nurse, whom we will call the ophthalmic nurse, for without this essential element in such a service, I believe that progress is almost impossible. By an ophthalmic nurse I mean one whose character and training will make plastic material, from which may be molded an assistant of earnestness, good judgment, and delicacy of touch, for without these characteristics no nurse can be of much service to the ophthalmic surgeon. She should, therefore, be carefully selected from the other nurses, and her term of service in the eye and ear department should not be less than 3 months, and more, if possible. If there is sufficient eye and ear work in the hospital to warrant it, she should devote her entire time to the service, but if not, she should belong primarily to this service, and secondarily, she may do other hospital work of an absolutely clean character, that will not interfere with her regular ophthalmic service. If there is sufficient material, 2 or more nurses might be detailed to work in this manner in the eye and ear department, but as the number of such patients in a general hospital will rarely exceed 20, 1 nurse will probably be sufficient.

It should be the duty of this nurse to perform personally all the nursing necessary in the eye and ear department. Of course, such services as the administrations of drugs, baths, sweats, collecting of specimens for urinalysis, etc., should be performed by the ward nurses, but the ophthalmic nurse or interne should be held responsible for them, and see that such orders are faithfully carried out. The ophthalmic nurse should not personally attend infectious cases, for obvious reasons; such patients may be cared for by the ward nurses, or by especially detailed nurses, to whom careful instructions should be given, but the ophthalmic nurse should be responsible for the faithful discharge of their duties, and she should consequently supervise the work. The ophthalmic nurse should always be on hand to make the rounds with the attending ophthalmic surgeon and the interne surgeon, and should carry with her a tray, upon which should be placed everything that will be necessary in the daily dressing of the patients. She should not have to run here and there to get this bandage and that solution, but should remember that time is valuable, and that everything must be close at hand. She should be able to vouch for the cleanliness, sterility, and freshness of everything upon her tray, and should give this matter her personal and earnest attention, remembering that while in general surgery a little suppuration in a wound need not necessarily prove disastrous, in ophthalmic surgery, particularly in cataracts and iridectomies, we must secure *perfect* healing, and the slightest infection will almost certainly ruin everything. She should learn the knack of putting solutions and ointments in the eye, or irrigating the eye, or cleansing an eye without injuring it, and of properly adjusting a bandage. She should understand how to use hot and cold applications, how to syringe and irrigate an ear, how to dry an ear, the use of the head mirror and the aural speculum. She should learn these and many other things too numerous to mention and so trifling as to appear insignificant, and yet of great importance if our patients are to acquire the best results. All these things the attending surgeon must take pains to teach the ophthalmic nurse from day to day as the rounds are made, remembering that while it may be a hardship to go over this ground 3 or 4 times a year as each nurse comes on, it is yet much easier than to have no ophthalmic nurse at all, and to endeavor hopelessly to impart fragments of information, that will be soon forgotten, to all the nurses in the hospital as he meets them from time to time in the different wards. In the intervals between the visits of the attending

¹ Read by title at the Memphis meeting of the Mississippi Valley Medical Association, 1903.

surgeon, the ophthalmic nurse should faithfully follow out his orders, such as putting medicines in the eye, changing bandages, cleansing eyes, etc., and should inspire the attending surgeon with a sense of confidence and repose that her duties are well and faithfully performed. The ophthalmic nurse should always be present with the surgeon when he performs operations, not, perhaps, as the chief nurse of the operating-room (whose duties are never supposed to be usurped), but as her chief assistant. In this manner she becomes familiar with operative work and interested in the cases, and will be almost certain to perform better work in the subsequent care of the patient than could otherwise be the case.

A week or 10 days before the retiring ophthalmic nurse goes off duty, the new ophthalmic nurse should be assigned to the department, to make the rounds with both the attending surgeon and the retiring ophthalmic nurse, for by so doing she becomes familiar with the work, and the establishment of new relations is accomplished with the least friction to all parties concerned. One great advantage in the teaching of ophthalmic nurses in this way is the education of women in this line of work, so that after graduating, surgeons can secure their services in private cases, in which patients prefer to remain in their own residences during their term of illness, a fact which I am sure will be greatly appreciated by those who, from time to time, have been compelled to employ nurses to care for ophthalmic cases, who were totally unacquainted with the requirements for this character of work.

It is almost unnecessary to say that one or two of the house internes should be assigned to duty in the eye and ear department, and that he or they should represent the attending surgeon in the hospital during the latter's absence, and should be held primarily responsible for the work of the department.

In most general hospitals the eye and ear department plays but an inconspicuous part, and, therefore, does not present many claims for financial and other considerations upon the part of the management. A few cases a year do not appear to the mind of the ordinary trustee or superintendent a valid argument for the expenditure of much money for instruments and appliances. Unless endowed, a hospital must run upon business principles, and must show at least some funds upon the right side of the ledger; therefore, the tendency is, and should be, to appoint men on the staff who are not only men of standing and ability, but also men who can appreciably increase the hospital income. Therefore, if eye and ear surgeons desire good services, with financial assistance and other considerations extended to them from the management, they should on their part establish their claims to such favors by organizing and maintaining a live department. This can be accomplished in several ways. First of all, I would emphasize the importance of the concentration of work in one hospital. I regard connections with various hospitals as extremely unwise, both from the standpoint of the surgeon and the hospital, as, if connected with various institutions the surgeon consumes much time in going from one to the other, and he is continually working in a variety of elements, none of which can be of the most desirable character. The eye and ear surgeon, even though in full practice, will hardly have a very large number of private hospital cases on hand at any one time; he can then best subserve his own ends by concentrating at least the very great majority of his cases in one hospital, to which he can devote his time and attention, and where he can erect a service that will be a credit and satisfaction to himself, and an encouragement to the institution. It certainly needs no argument to insure conviction that a surgeon can work best and to the highest benefit of his patients in an atmosphere where internes, nurses, attendants, etc., are familiar with his every want, and where he is surrounded by those instruments and appliances that make work easy, and where experience has shown that after-care and treatment will be followed out according to his desires.

Every effort should be made to secure as colleagues in the eye and ear department men not only of high professional and personal character, but also men who are broad-minded and congenial to work with, and who will earnestly labor for the upbuilding and success of the department, and who can keep enough patients in the hospital materially to aid toward the

end in view. It is an extremely poor plan as vacancies occur, to pursue the narrow-minded policy of placing men upon the staff who are harmless and negative, and who are not strong enough professionally presumably to injure the prospects of the older incumbents. The best possible material should be secured, as everything that enhances the importance of the department benefits every one connected with it. Two or 3 or 4 men of ability, rectitude, and energy working together as a unit, conferring together frequently as to ways and means, and considerate as to each other's feelings, can build up an eye and ear department in *any* hospital that will be a credit to themselves and an object lesson to many. But few men in this specialty can command enough private hospital cases to make of this department a real power, while 2 or 3 or 4 surgeons, largely concentrating their work in one institution, can show a record at the end of the year that will place them in a position to acquire anything in the way of instruments and privileges that it is within the power of the trustees and superintendent to bestow.

The upbuilding of an operative clinic upon definite days and hours I regard as one of the surest methods of welding together an eye and ear department, and making it a credit and power to all parties concerned. By this I do not mean a one man clinic but rather a department clinic, at which all the eye and ear men in the hospital are expected to participate. But few eye and ear surgeons can command enough operative material to interest regularly a class once a week for 2, 3 or 4 hours, and anything less is not sufficient; while 2, 3 or 4 surgeons can usually, between them, produce sufficient material to make a fine clinic, run with the regularity of clockwork. A day and an hour should be selected that will be reasonably convenient for all, and this time should be retained year after year with the possible exception of cessation during the summer months. After a time the clinic will become known and recognized by profession and laity, and will be a source of pleasure to the surgeons, and profit to the students and visiting physicians. At this clinic all the attending staff should participate as they have material and frequently all will operate in a single afternoon, and in this very feature resides one of the most delightful elements of the plan—the intimate mingling together in an operative clinic once a week, of colleagues of similar tastes and desires, the intermingling of ideas and opinions, and the useful observation of each other's work and method. I, myself, am a participant in a plan of this nature and I can truthfully say that it is to me the brightest spot in my professional life. The number of clinical days in the week may be increased from 1 to 2 or 3 or more days in the week, provided sufficient material is presented, but it is better to have one sure and full day than several uncertain days, with a paucity of operations. Let the profession and students realize that upon a certain day and hour at a certain hospital they may depend upon seeing plenty of good operative work, and the success of the clinic is assured. I believe it to be an excellent plan to encourage the nose and throat men on the staff to participate in these clinics as the branches are closely allied, and this added element will materially aid in all of the desired results.

Another feature tending toward the upbuilding of an eye and ear department in a general hospital, is the opening and encouraging of a good live dispensary. This will sensibly aid in supplying material for the operative clinic. I do not, however, wish to be understood as advocating the surrender of operative material from the dispensary oculist and aurist to a member of the hospital staff for use in the clinic. On the contrary I would open the clinic to the dispensary men on equal terms, and urge them to operate and lecture whenever they can furnish suitable material either from the dispensary or elsewhere. I would likewise extend to them the full privileges of the hospital and would urge the dispensary staff to organize, and to have regular meetings, and that the president of the dispensary staff be invited always to attend and participate in the meetings of the hospital medical board, in order that the two bodies may come closer together, and better understand each other's aims and necessities. By treating the dispensary staff in this manner and letting it realize that it is a part of the general institution, and that every one is interested in its existence and success, the highest interests of all will be

best subserved. Finally, I believe that the success of an eye and ear department can be materially assisted by inviting men to take part in the operative clinics, who have no official connection with the hospital. If for instance, a colleague in or near your city has performed conspicuously good work along the line of cataracts, lid surgery, mastoid work, etc., invite him once or twice a year to the clinic to demonstrate his methods to your class, and acknowledge the excellence of his work, in a manner that will show you to be broad minded and generous and above petty and ignoble jealousies. This act frequently repeated will not only add material, variety and interest to the clinic, but will go a long way toward creating in your city a fraternal and kindly sentiment that will be reciprocal in its nature, and add much toward the better understanding of rival colleagues and the establishment of professional relationships which will be most delightful in their character.

Much remains to be said upon this interesting and important subject, but enough has been mentioned to indicate a general policy which, if carried out, will, I believe, produce good and satisfactory results. The plan is not an ideal and optimistic dream, for in St. Luke's Hospital, where I do most of my operating, it has been carried out in detail to the great delight of my colleagues, Dr. Casey Wood and Dr. Thomas Woodruff, with whom I have worked for some years with ever-increasing gratification and respect, and to myself. Great results may be obtained if earnestness and unity of action be observed, and from a small beginning in a general hospital, with patients scattered in every ward, an eye and ear department may grow until a portion of a building or a separate pavilion may be dedicated to its use, where work of the best and highest character will be performed by a large staff of energetic and congenial workers.

3.—See *American Medicine*, Vol. V, No. 22, p. 862.

4.—See *American Medicine*, Vol. V, No. 20, p. 778.

5.—See *American Medicine*, Vol. V, No. 22, p. 862.

6.—**Echinococcus Cyst of the Liver.**—B. Holmes describes the life history and geographic distribution of the parasite, and the clinical history of the host, and gives an extended report of a case in a young girl who had been erroneously treated for tuberculous hip-joint disease, and on whom an exploratory laparotomy was done for a tumor of the liver with enormous enlargement of that organ. After evacuation of 2 cysts, there was rapid convalescence from the operation, and complete return to perfect health. America cannot hope to remain free from the echinococcus for long. All association with dogs, especially imported dogs, is attended with danger; their presence about truck farms and gardens, grocery stores, and kitchens is dangerous and filthy. Medical treatment is useless, as are also tapping and washing out of the cyst. The only surgical treatment is laparotomy, the opening and evacuation of the cyst, and probably tamponade and drainage. [H.M.]

7.—See *American Medicine*, Vol. V, No. 22, p. 859.

8.—**History and Etiology of Migraine.**—G. M. Gould criticises this meaningless name for a symptom-complex of infinite variability whose etiology and pathology, according to current literature, are unknown, and for which no treatment has availed. He traces the disease through medieval and

ancient literature and believes its relief to have been the motive in prehistoric trephining. He discusses the various classifications, the prodromal symptoms, the typical attack, and the special ocular symptoms preceding and accompanying the head pains and nervous and digestive symptoms, and refers to the article of G. Martin which will one day be recognized as epoch making, Martin having from his own experience discovered the relationship of sickheadache to astigmatism and then verified the observation on 352 reported cases, low astigmatisms being the rule in these. The apparent relation of migraine to the sexual organs is explicable by the increase in eye work and in eyestrain at the critical sexual periods, and women have been more subject to it than men because they have done more near work with the eyes. The writer points out the significant relation between gastric symptoms, literary work, and the invariable outdoor or hydrotherapeutic treatment. The close connection between migraine and excess of uric acid suggests that the latter is dependent on eyestrain also. The pareses, paralyses, anesthetics, and psychic disorders described as characteristic of migraine have often been noted by the author in his private practice as resulting from ocular defects. Migraine in its typical and atypical forms is almost always but one of the manifestations and results of eyestrain and may be cured by lenses correcting the astigmatism on which the disease depends. [H.M.]

9.—**Lipoma Arborescens Tuberculosis.**—C. G. Levison reports a case in which the extensive involvement required exposure of the whole knee-joint in order to complete removal of the growth. Operation was followed by a most satisfactory result, a flexible joint which could be used without support. He describes the macroscopic and microscopic appearances of the villi. No tubercle bacilli were found, possibly on account of the specimen having been kept in formalin several months prior to examination. [H.M.]

Boston Medical and Surgical Journal.

1. Clinical Lecture on Epithelioma at Massachusetts General Hospital. J. COLLINS WARREN.
2. The Prevailing Conception of Degeneracy and Degenerate, with a Plea for Introducing the Supplementary Terms Deviation and Deviate. G. L. WALTON.
3. Cancer of the Rectum: Combined Abdominal and Perineal Operation. CHARLES A. POWERS.

2.—**Degeneracy and Deviation.**—G. L. Walton objects to the term degeneracy on account of its association with profligacy, perversion, crime, epilepsy, insanity, and idiocy. The term "superior degenerate" has caused confusion even among special students. Degeneracy has come to include every form of variation from the average normal, from flecks on the iris and astigmatism, to insanity. Have we not drifted into recording facts in such a way as to have an opinion? If so, is it not reasonable, unless we are dealing with undoubted degeneracy, to record deviations as deviations? The stigmas do not necessarily indicate deterioration. The downward is not the only direction, as the word degeneracy would imply, in which deviation may be found. [H.M.]

3.—**Combined Abdominal and Perineal Operation for Rectal Cancer.**—C. A. Powers reports that a woman of 45 had suffered from the symptoms of rectal cancer for 6 months. Examination showed the cancerous growth and the invaded gut movable. The patient being thin and small, though of good strength, a combined abdominal and perineal operation was decided upon. The operation described by Mayo,¹ and attributed by him to Gaudier, of Lille, was performed. Powers describes the operation in detail. The patient was under chloroform anesthesia for 3½ hours, and suffered no profound shock. The anus and 11½ inches of the lower bowel were resected, together with the glands and gland-bearing tissue surrounding the rectum in the pelvis. An artificial anus was established in the left inguinal region at the same operation. The patient made a good recovery, and 6 months after the operation was doing ordinary domestic service. Microscopic examination showed the removed tumor to be adenocarcinoma. [A.B.C.]

Medical Record.

January 23, 1904. [Vol. 65, No. 4.]

1. On Cytodiagnosis in Nervous Diseases. CHARLES L. DANA and F. W. HASTINGS.
2. Lymphocytosis of the Cerebrospinal Fluid. JOSEPH FRAENKEL.
3. Thorium: A Radioactive Substance with Therapeutic Possibilities. SAMUEL G. TRACY.
4. A New and Simple Phototherapeutic Lamp. HENRY G. PIFFARD.
5. Early Operations in Abdominal Troubles. EDMUND M. POND.
6. Two Cases of Abdominal Traumatism. A. B. ATHERTON.
7. Common Duct Stone without Characteristic Symptoms. GEORGE EMERSON BREWER.

1.—Cytodiagnosis in Nervous Diseases and the Technic of Cell Diagnosis.—C. L. Dana and F. W. Hastings contribute a somewhat technical article on this subject. The cerebrospinal fluid is obtained by lumbar puncture, after the method of Quincke. The fluid thus obtained is studied and conclusions arrived at. They assert that cytodiagnosis of the cerebrospinal fluid seems likely occasionally to be of great help in diagnosing the doubtful cases of paresis and of tabes, in the early stage. It will be of help in determining whether the person has had syphilis, and whether certain symptoms indicating the invasion of the central nervous system by this infection are correct. In spinal syphilis, as shown in cases of syphilitic meningomyelitis, or Erb's spinal paralysis, there is an increase in the cell count, and if trauma can be excluded, the presence of specific infection may be inferred. This method should be of help in determining the activity of the process. If there is any actual inflammatory change going on, it will be shown by the presence of the polynuclear leukocytes, while in the ordinary conditions of specific infection, only mononuclears are present, with a proportion of polynuclears of not over 5%. It must be remembered that there are some cases in which, although paresis or tabes is present, there are no cells found, at least, on the first examination. Widal asserts that if 2 or 3 examinations are made, the lymphocytosis will always be discovered. Hastings describes in detail the method of doing lumbar puncture and securing the fluid. [A.B.C.]

2.—Lymphocytosis of the Cerebrospinal Fluid.—J. Fraenkel reports 33 cases of successful puncture for cerebrospinal fluid. In 7 cases of tabes of long duration a more or less marked increase of lymphocytes was found. In 4 cases of general paresis, leukocytosis was marked, as it was also in 6 out of 7 cases of multiple sclerosis. In these last no polynuclear cells were seen. Two out of 3 cases of syphilitic disease of the central nervous system and one of syphilitic brain tumor showed marked leukocytosis. In all the other cases, paralysis agitans, brain tumor, hysteria, poliomyelitis, discharge of cerebrospinal fluid from the nose, aural vertigo with peripheral facial palsy, and hereditary syphilis without nervous symptoms, the fluid was free from corpuscular elements. The tapping was done under ethyl chlorid with the patient bent forward. The most suitable space is between the third and fourth lumbar vertebrae near the middle line. Occasionally one has to wait 30 seconds to a minute until the fluid appears. [H.M.]

3.—Thorium as a Radioactive Substance.—Samuel G. Tracy states that this metal was first discovered in 1828 by Berzelius, but until recent years its scarcity has prevented its use. Its present greatest use is for the production of incandescence in the Welsbach mantle. That it is radioactive can be proved by many experiments. He has proved this by placing metal substance such as a key on a sensitive plate in a dark room and exposing this to the action of the metal for a varying number of hours, depending upon various conditions explained, a thoriograph can thus be made. Recently scientists have proved that the emanations from this element are antiseptic and antifermentative. It has been shown that grape juice when exposed to radioactive matter will not ferment, likewise oils of juniper, origanum, etc. These oils ferment and decompose in a few days if left to light, but after treatment with thorium, even in the presence of light, they were preserved for several weeks. Lately it has been suggested to treat tuberculosis by means of inhalations of thorium, based upon its antiseptic and antifermentative action. [A.B.C.]

5.—Early Operation in Abdominal Trouble.—Edmund M. Pond's article advocates early operation in abdominal troubles, and in this article he discusses the question largely as it pertains to general practitioners. He holds that the general

practitioner is often at fault in his failure to make an early diagnosis, or at least to recognize serious trouble, and therefore he fails to call in a consulting surgeon. In the article he relates a number of instances in which disaster resulted from this very failure. If the surgeon is called too late and gives the patient the last desperate chance by operation he is often blamed for the result, whereas the real fault lies in his not being called sufficiently early. [A.B.C.]

6.—Two Cases of Abdominal Traumatism.—A. B. Atherton reports that a farmer of 48, in endeavoring to discharge an old musket, rested the butt end of the gun against his abdomen on the right side, and it was discharged with a violent recoil. The writer was called, and after having the patient taken a distance of 10 miles to a hospital, he was operated upon and a laceration of the intestine with extensive extravasation into the abdominal cavity found; the rent was closed, thorough irrigation of the abdominal cavity accomplished, and though a fecal fistula persisted for many weeks, the patient finally made a complete recovery. The other patient was a man of 45, who had received a 22-caliber bullet wound in the loin between the ninth and tenth ribs. Within the first 12 hours the patient vomited much blood, the abdomen was opened, and the bullet was found to have traversed the stomach and lodged in the omentum. It was found entangled in the omentum, removed, and the patient made an uneventful recovery. [A.B.C.]

1. Psychic Healing, or, Properly Speaking, the Treatment of Disease or Supposed Disease by Mental Influence. EDWARD WALLACE LEE.
2. The Relation of Early Diagnosis and Treatment to the Prevention of Tuberculosis. F. M. POTTENGER.
3. A Simple and Inexpensive Apparatus for Lifting and Moving Helpless Patients. FREDERICK H. SAWERS.
4. Concerning the Accuracy of Percentage Modification of Milk for Infants. DAVID L. EDSALL and CHARLES A. FIFE.
5. Some Investigations of a Bacterial Treatment of Tuberculosis. STEPHEN J. MAHER. (Continued.)

2.—Prevention of Tuberculosis.—F. M. Pottenger calls attention to the great importance of early diagnosis in the prevention and treatment of tuberculosis. It is not necessary to wait until bacilli appear in the sputum. A skilful physician should be able to detect the disease from the clinical history and the findings of a physical examination. If these are insufficient, the tuberculin test can be used with confidence and safety. The reason that early diagnosis is so important in relation to the prevention of the disease changes completely as it advances. At first it is a pure tuberculosis, later mixed infection makes the picture more complex and the prognosis more grave. Sanatorium care affords the best conditions for a cure. Latest statistics show that over 30% of all cases thus treated are permanently cured. [C.A.O.]

3.—Apparatus for Moving Patients.—A simple and inexpensive apparatus for lifting and moving helpless patients has been devised by F. H. Sawers. He attached a 6-foot track to the ceiling and used an 8-wheel carrier, such as is used for overhead carrying track systems; a tackle and wood frame, as a spreader, fixing the center bolt with 2 nuts; a canvas seat with opening, and straps of stout webbing. When the canvas has been adjusted, the patient may be lifted easily, turned on the swivel and moved on the track away from the bed. The apparatus was constructed for a patient suffering from a cerebral hemorrhage with complete bilateral paralysis. His weight was 206 pounds. Cuts illustrative accompany the article. [C.A.O.]

4.—Modification of Milk.—D. L. Edsall and C. A. Fife have undertaken a series of chemic examinations of milk mixtures, with the purpose of learning whether there are any important errors in the percentage method of feeding, as it is usually carried out; and if errors exist, to determine their sources and, if possible, the manner in which they may be corrected. In carrying out this purpose they analyzed 88 different milk mixtures. The chief source of error is the variation in the composition of different milks and creams; particularly in the fat content of the creams. Another error is undoubtedly found in the person who does the measuring and mixing. The general conclusions are: 1. Milk modifications, under the best

of conditions, will often vary 0.2%, occasionally 0.3% from the prescribed formulas, with modifications of medium strength. With low modifications, the error will be correspondingly less; and with high modifications, correspondingly somewhat greater. 2. Home modifications are, within the limits just mentioned, trustworthy, if they are made by a clear-headed and careful person, from milks and creams of a chemic composition that is known to be reliable. 3. If the composition of the milks and creams used is not known, or if one cannot be sure that the modifier is careful and clear-headed, home modifications are likely to vary greatly from the formulas prescribed. 4. Laboratory modifications appear to be satisfactorily accurate; and unless the milks and creams, as well as the person doing the modifying at home, can be fully trusted, laboratory modifications, when available, are much more reliable than home modifications. [C.A.O.]

1. Interscapulothoracic Amputation for Sarcoma. CHARLES A. POWERS.
2. Prevention of the Spread of Ringworm. F. H. BEADLES.
3. Cryoscopy of Urine: The Method of Claude and Balthazard. F. BURTHE.
4. The Pathology and Treatment of Osteoarthritis. EDWARD M. MERRINS.
5. Bovine Tuberculosis. J. W. KIME.
6. Neurasthenia. JOSEPH N. STUDY.

1.—Interscapulothoracic Amputation for Sarcoma.—C. A. Powers reports the case. A man of 56 fell and fractured the upper part of the left humerus, and was properly treated. Three months later he noticed a small lump at about the seat of fracture, anteriorly, and 2 months later it appeared to be increasing in size. A small bit of the growth was removed and examined microscopically. The tissue was found to be sarcomatous, and amputation at the shoulder-joint was advised. This the patient refused. The tumor continued to grow in size, but the patient would not consent to operation until 9 months after its first appearance. Intrascapulothoracic amputation was done, the cords of the brachial plexus being cocaineized before they were divided. The patient recovered satisfactorily from the operation. A footnote states that the patient died 6 months after operation from metastatic sarcoma of the hip. Powers believes that in some instances a hitherto unrecognized sarcoma of the bone may lead to fracture, and the latter be later blamed for the occurrence of the malignant disease, but he is convinced that in this case the fracture preceded, and in all probability contributed to the occurrence of the sarcoma. [A.B.C.]

2.—Preventing the Spread of Ringworm.—F. H. Beadles points out some of the mediums of transmission for *Microsporon audouini* and *Trichophyton*, the large and small spore fungi which cause ringworm. Among these are mentioned the cat, dog, bird, horse, cow, mouse, sheep, and others. He holds that these domestic animals are more frequently responsible for transmission than is generally supposed. The barber shop is another frequent disseminator of this disease, not by the razor, but by the barber's hands, towels or lathering brush. In public schools the disease is often conveyed readily from one child to another, and the writer holds that it has long been urgent that medical inspectors be appointed for public schools to see that this and other diseases are properly recognized and attended to. [A.B.C.]

4.—Pathology and Treatment of Osteoarthritis.—Edward M. Merrins refers to the numerous varieties of this disease which have been pointed out by certain investigators, but practically they are all confined under 2 heads. 1. Rheumatoid arthritis, which is regarded as a constitutional disease usually of toxic origin. It begins with involvement of the synovial membrane, later involving all the arthritic tissues in an atrophic process. The joint becomes constricted, deformed, limited in movement, and sometimes ankylosed; muscular wasting and shortening may occur. 2. Osteoarthritic affections. These may be polyarticular, and the brunt of the disease falls upon the cartilages and articular ends of bones. In bone the synovial membranes, as in rheumatoid arthritis, the changes induced are destructive and hypertrophic, the cartilages be-

come fibrillated and eroded and hypertrophied at the margins being heaped up in irregular nodules. Later these nodules may undergo calcification or ossification. The forms of this disease are Heberden's nodes, spondylitis deformans, and malum coxae senilis. These and kindred lesions are all considered in detail. In the treatment, drugs are of small value; regulated diet and hygiene, together with massage and superheated air, appear to give the best results in arresting the process. [A.B.C.]

5.—Bovine Tuberculosis.—J. W. Kime believes the milk of tuberculous cows as dangerous as the sputum of a tuberculous patient and that cases derived directly from the cow are more rapidly fatal than those from human infection. In half of his own cases there has been no family history of tuberculosis or no close contact with the disease and fully as many cases have come from the country as the city. It is estimated there are at least 2,500,000 tuberculous cows in the country. Milk from such is unfit for use whether the udder is diseased or not, and is especially dangerous to children. All dairy cows should be tested annually, notwithstanding the bitter opposition of dairymen. The unfortunate utterances of Koch have materially lengthened the time necessary to stamp out the disease in our dairy herds. [H.M.]

6.—Neurasthenia.—J. N. Study acknowledges that this condition is rapidly growing, modern civilization being responsible. Americans lead all nationalities. The lack of moral training in childhood and heredity plays an important part. Improper suggestion by designing advertisers or ignorant people prepares in some cases for the final breakdown. Well-marked cases seldom appear before manhood or womanhood, increasing up to 40 and 50. The symptoms are legion and may mask grave mental affections. The treatment should be both moral and medicinal. Most of these patients regain their physical and mental status to a greater or less extent, though large numbers become chronic invalids, and some cross the border line of insanity. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Pseudoappendicitis and Membranous Enterocolitis.—It has often been a matter of conjecture whether or not there exists a relationship between appendicitis and enterocolitis. Potain and Bottentnit deny any connection between the two affections and in a statistic of 460 cases of membranous enterocolitis the latter authority only found one in which appendicitis occurred as a complication. Out of 53 cases of enterocolitis Dieulafoy was unable to discover any symptoms pointing to a diseased condition of the appendix, while on the other hand Robin admits a common origin of both maladies, considering them as an ultimate result of certain types of dyspepsia. In children, Hutinel has often seen an appendicitis enter upon the scene during the progress of an enterocolitis, while Vorbe has collected 32 instances in which the former affection resulted from a membranous enterocolitis. Lyon also upholds the *liaison* between the two processes and of 5 cases of appendicitis he records 2 in which the patient previously suffered from a membranous colitis. The diagnosis must frequently be a very delicate affair, either because the attack of pseudoappendicitis appears in the midst of otherwise perfect health, or on the other hand, when it arises during the course of an apyretic chronic enterocolitis. The early symptoms very closely simulate a true appendicitis and consist of vomiting, tympanism and elevation of the temperature reaching as high as 39° or 40° C., while added to these we have a small and frequent pulse and a pinched facies. To add to the confusion, the greatest point of tenderness will be found in the region of the cecum and very naturally the diagnosis of appendicular inflammation is made. Such cases have been and are needlessly operated on, much to

the chagrin of the surgeon, who finds a normal appendix but a considerable thickening of the cecum and ascending colon. These cases, if watched, will soon show the presence of numerous membranes, of a mucous nature, in the stools. De Langenhagen is of the opinion that true appendicitis is most infrequently met with in membranous colitis, but what is of ordinary occurrence are attacks of pseudoappendicitis, which are nothing more or less than pain localized in the ileocecal region due to an enterocolitis. These attacks of pain so frequent in membranous colitis have a maximum point of intensity and often acute exacerbations, in a given portion of the large intestine, such as the sigmoid flexure, at the middle of or at the flexures of the transverse colon, or at the cecum. In the latter case the clinical picture will be much like that of appendicitis, so much so, that only an exploratory incision will reveal the true condition of affairs. The all-important question, therefore, is to differentiate between the two conditions and thus avoid an error in diagnosis. It is pathologically possible for the appendix to become involved in a membranous colitis, but under these circumstances a differential diagnosis may be made by detecting the presence of greatest pain of the 2 flexures of the transverse colon, these points being quite as tender to pressure as the region of the appendix. Beside, pain may be elicited over the entire course of the large intestine. These attacks of pain are more frequent in children than in adults, for young subjects show a greater reaction and in them alarming symptoms occur, such as fever, vomiting and pain predominating in the cecal region, so that nothing is lacking for a diagnosis of appendicitis. But in enterocolitis the pain is never distinctly localized to the right iliac fossa. And lastly, one should never neglect rectal examination which, as is well known, is one of the greatest aids in diagnosing appendicitis.

REVIEW OF LITERATURE

Glycolysis in Its Relation to Diabetes Mellitus.—R. Lépine¹ gives a critical review of the subject of glycolysis. The fault in diabetes mellitus probably lies in the first act of the glycolytic process. This act is not a simple oxidation, but involves the action of a special oxidizing ferment. Among the intermediary products of glycolysis are oxalic acid, lactic acid, and alcohol. The author has devised a method of measuring the glycolytic power of the organism, based on the fact that the blood will continue to live for some time after being withdrawn from the vessels. His method includes defibrination of the blood, and subsequent measurement of its glycolytic power. The latter is diminished in asphyxia, cerebral disturbances, and disease or destruction of the pancreas. It is augmented in states of mild increase in the alkalinity of the blood, in excitation of the pancreas, and ligation of the duct of Wirsung. The theory of diabetes, recently propounded by Cohnheim and affirmed by the author, maintains that the pancreas, especially the islands of Langerhans, produce an internal secretion which is not directly glycolytic but becomes so when acting in conjunction with a ferment produced in muscle. [B.K.]

Are Koplik's Spots Reliable Early Symptoms of Measles?—Aronheim² found Koplik's spots in only 7 out of 150 cases of measles examined. [E.L.]

Pathology of Acute Poliomyelitis.—P. A. Preobrazhensky³ infers from literature and from his own researches that (1) acute poliomyelitis can result from lesions of the lateral anterior artery as well as from lesions of the sulcocommissural arteries; (2) acute myelitis and poliomyelitis may be identical processes, depending on the accidental localization in this or that arterial district; (3) the same infection may produce interstitial as well as parenchymatous changes of varying intensity, hence a classification of myelitis according to anatomic lesions is unreliable; (4) the question as to the existence of acute parenchymatous myelitis must remain an open one, because we

cannot distinguish closely between acute degeneration of the nerve elements and their acute inflammation; (5) in human rabies there are no specific changes of the nervous system which would permit a postmortem diagnosis. [L.J.]

The Hemostatic Effect of Gelatin.—Leopold Moll⁴ showed experimentally that when gelatin was applied locally to a bleeding surface, or subcutaneously (intravenously) during existing hemorrhage, or on the day before an expected hemorrhage, that the fibrinogen was increased, and agglutination of the blood-corpuscles occurred. He found a constant parallelism between the number of leukocytes and the amount of fibrinogen. [J.H.W.R.]

Laryngeal Crepitation as a Sign of Pulmonary Tuberculosis.—Remouchamps⁵ describes a sign which he terms "laryngeal crepitation," and claims it to be present in all cases of pulmonary tuberculosis, frequently before any other signs or symptoms can be elicited. The physician faces the patient, who is directed to open his mouth slightly. The physician places his right hand on the patient's left shoulder, and his left thumb on the patient's chin; then approaches his left ear toward the mouth of the subject. A fine crepitation may be heard, which is simply an augmentation of the sounds produced in the tuberculous lesions. It is heard during inspiration and expiration, more pronounced in the latter. Sounds may be heard in other affections of the lungs, but they have not the fine crepitan character of the ones described. [B.K.]

Pyocetanin in Noma.—There are in Russian literature 2 reports of noma cured by blue pyocetanin. D. T. Achwlediani⁶ reports his second case (the third in literature). A child of 3½ years was attacked by noma. The ulcer started at the right nostril and destroyed the soft nasal parts, spreading to the angle of the mouth. Pyocetanin was ordered in a 1% solution, to be frequently applied on compresses. Prompt improvement followed, the very next day showing a cessation of further spreading of the ulcer. In 4 days the ulcers were clean and healthy, and in 2 weeks the child was cured. [L.J.]

Widal Reaction in Catarrhal Jaundice.—F. Köhler⁴ has noted a positive Widal reaction in cases of catarrhal jaundice, especially when due to a colon infection. The groups of diseases which may give a Widal reaction are typhoid fever, liver diseases, in which bile enters the blood; colon infections, and certain pneumococcus and meningococcus diseases. The Widal reaction seems to have lost considerable of its value, when all the recent investigations are grouped together. [E.L.]

The Diaphragmatic Phenomenon of Litten.—S. Pugliesi⁵ calls attention to its constancy in health. It is the passage of a linear shadow over the thoracic wall, which may be modified in disease as far as being almost absent; in hemiplegia on one side, in pulmonary or hepatic disease accordingly. A differential diagnosis is made between a subphrenic tumor and a pleuritis. The sign, he thinks, were better called the "pneumophrenic phenomenon of Litten." [T.H.E.]

Paroxysmal Tachycardia.—Under the term "Herzjagen," A. Hoffman⁶ has described a form of paroxysmal tachycardia, marked by extreme rapidity of the heart's action, preceded and followed by irregularity. The same author now reports further observations made on 6 additional cases. No organic disease could be demonstrated in any case. The apparent causes seemed to be bodily exertion in 3 cases, psychic emotions in two, and alcohol with tobacco in one. The attacks begin and end suddenly, the heart's action being regular during them. In 1 case a Röntgen ray examination showed the excursion of the ventricle to be very much reduced, owing to incomplete diastole. On auscultation no abnormality was noted, with the exception of embryocardia. The blood-pressure was practically the same during and between the attacks. Polyuria, without albumin or sugar, was a frequent accompaniment of the attacks. There was very little general disturbance after the attacks. The frequency of the pulse was almost exactly twice as much during the attacks as immediately after

them. The tachycardia is ascribed by the author to an alteration in the excitability of the heart muscle, the contractility and conductivity both being increased. The impulses to contraction probably arise from the roots of the great veins, and travel toward the heart. Normally, every second impulse finds the heart muscle in a refractory state; but in this condition the contractility is increased, and each impulse becomes a contraction. [B.K.]

The Nature and Treatment of Delirium Tremens.—J. F. Kelly¹ gives the results of observations upon the alcohol habitues, who during the past 5 years have been admitted and readmitted to the State Hospital at Cleveland. He particularly emphasizes the significance of the so-called prodromes or first stage of the condition marked by pallor, anorexia, tremor, and muscular weakness, general hyperexcitability, restlessness, fear, sleeplessness, and usually albuminuria. The second stage, heralded by the advent of hallucinations and illusions, is only a culmination, often needless, of the first. While alcoholic habituation is the basic factor in the etiology of delirium tremens, and while there is nearly always a history of unusually heavy dissipation just before an attack, Kelly believes that a more immediate and determining factor, always constant and of great importance, is the sudden withdrawal of alcohol, either wholly or in large part. This, if true, accounts for the numerous cases of delirium tremens following accidents to persons during a debauch, part of the treatment usually being the sudden entire withdrawal of alcohol. Kelly's assertion, that delirium tremens is an alcohol abstinence psychosis is based on the results of 2 plans of treatment—sudden and gradual withdrawal of alcohol. In his experience the symptoms characterizing the first stage, particularly tremor, fear, and loss of appetite, have invariably disappeared when alcoholic stimulants were given in sufficient quantities. Doses sufficient to control the symptoms should be given and entire withdrawal can usually be attained within a week. Nux vomica, capsicum, and the bromids are indicated at times, but no good results have been secured from the use of chloral or morphin. [A.G.E.]

Lime Dust Inhalation and Pulmonary Tuberculosis.—P. Reckzeh² reviews the literature and gives his views on this subject. It has been observed that laborers suffering from pulmonary tuberculosis whose expectoration showed the presence of tubercle bacilli, were cured of all symptoms after working several months in quicklime dust. In order to determine whether lime was of value in the treatment of tuberculosis, he subjected 8 patients who had tuberculous lung trouble to inhalations of lime dust. He gives in full the histories and symptoms of these patients. The inhalations were carried out as follows: Linen bags containing freshly burnt lime dust were suspended in the patient's rooms and beaten at frequent intervals. The dust set free in the air was inhaled by the patients for 15 minutes daily. The ears and eyes of the patients were protected in order to prevent irritation. From his investigations, Reckzeh concluded that inhalations of lime dust had no marked influence upon the temperature and body-weight. The physical signs remained unaltered, but the cough and the amount of sputum were lessened. The number of bacilli in the sputum varied, sometimes increasing and at other times decreasing. Some untoward effects occurred, such as headache, loss of appetite, and nausea. The author believes that lime dust is of little or no value in the treatment of pulmonary tuberculosis. [W.E.R.]

Significance of Infection, Heredity, and Disposition in the Etiology of Tuberculosis.—E. Schwarzkoff³ found that 61.25% of his cases of tuberculosis had a clear history of exposure to infection by association with careless tuberculous patients; while only 24.22% of nontuberculous patients showed such a history. This shows that infection plays an important part in the development of tuberculosis. Almost every one is exposed at some time to infection with the tubercle bacillus, but a repeated exposure seems to be required for infection to occur. The danger of a tuberculous subject for those associated with him may be entirely overcome by the necessary precautions in coughing and expectorating. Mere hereditary tendency has not

the slightest influence on the development of pulmonary tuberculosis; it is rather the simultaneous exposure to infection which is of importance. A series of harmful influences, such as child-birth and sedentary occupations in women and certain industries in men, is able not only to aggravate an already existing tuberculosis, but also to serve as a predisposing factor in its development. [B.K.]

Splenic Anemia with Transition into Lymphatic Leukemia.—S. M. Zypkin¹ reports such a case in a woman of 39 in whom a first examination of the blood showed the presence of 2,700,000 erythrocytes, 8,800 leukocytes, and 35% hemoglobin. The examination further showed 64.5% polynuclear; 22.4% large lymphocytes; 5.4% small lymphocytes; 6.4% mononuclear leukocytes with ungranulated protoplasm; and 1.3% of eosinophilic nuclear leukocytes. About 2 weeks later it was as follows: Erythrocytes, 1,550,000; leukocytes, 106,400; hemoglobin, 24%. The differential count was as follows: Polynuclear neutrophils, 11.9%; large lymphocytes, 64.7%; small lymphocytes, 6.3%; mononuclear neutrophils, 2.4%; mononuclear leukocytes with ungranulated protoplasm, 14.4%; eosinophiles, 0.3%. There was marked poikilocytosis in the erythrocytes, and a large number of normoblasts as well as megaloblasts. The nuclei were divided in the mononuclear leukocytes with ungranulated protoplasm. At the onset the case presented the symptoms of splenic anemia. It was differentiated from pernicious anemia by the presence of an enlarged spleen, which extended 4 fingers' breadth below the border of the ribs. The postmortem findings failed to show the characteristic appearance of pernicious anemia. A pseudoleukemia could be excluded, as the relative lymphocytosis in the preleukemic stage was not marked. He quotes Litten's case of pernicious anemia which became a case of leukemia, a second similar case reported by Waldstein, a third case of Gottlieb's, a fourth of Immermann, a fifth described by Körmöczy, and a sixth case of Gerhardt. Zypkin was only able to find 1 case in literature similar to his own—namely, that of Frizzoni. [J.H.W.B.]

Protective Effect of Antityphoid Inoculation.—A. E. Wright² publishes 2 tables, one compiled from the British army in India, and the other from that in South Africa. Both tables show that antityphoid inoculation has produced a reduction of 50% in the incidence rate of typhoid fever. The first table shows a reduction of five-sixths in the deathrate. [B.K.]

Morbus Kahler.—Bonardi³ gives the case of a woman of 28, which had its onset in an intermittent quotidian fever, initiating by chills, and giving way to profuse sweating. The liver and spleen were observed to increase in size by the second day. After this there was malaise accompanied by fugacious pains, often osteoscopic; then albuminuria developed. Tuberculosis, syphilis, and malaria were thought of. The writer observed tumefactions over certain bones, notably the frontal, sternal, costal, and clavicular, and an aggravation of the preceding symptoms. Albuminuria became albumosuria, with a proportionate ratio to the height of fever. The patient turned to excessive use of morphin. Another case, a man of 59, is given. He died after an afebrile period during which the quantity of albumose diminished in the urine. There is a differentiation required between Kahler's disease and osteomalacia. Necropsies in these cases not obtained. [T.H.E.]

Potential Sugar in the Blood.—If normal blood be maintained outside the body for half an hour at a temperature of 58° C. a certain amount of sugar is produced, for which the glycogen cannot be held responsible. This sugar comes from one or several carbohydrate molecules contained in the proteids. Lépine and Boulud⁴ give to it the name "potential sugar." They find that the blood in the left heart has more sugar, but less potential sugar, than that in the right heart; hence, some potential sugar must be liberated from the proteid molecule in the passage of the blood through the lungs. The same differences are observed between blood in the large arteries and that in the large veins. Hence, it is evident that one of the pathogenic elements of diabetes may be the instability of the proteid molecule. [B.K.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

EDITORIAL COMMENT

Local Anesthesia for Major and Minor Operations.—We are under the impression that local anesthesia is not as generally used as its superior safety over general anesthesia entitles it to be, especially for major operations. Matas' statement of the case, made some time ago, still holds, "An unfounded and scarcely justifiable scepticism still prevails among many excellent, skilled and otherwise progressive surgeons, who, having neither the inclination nor the patience needed to acquire the most advanced and effective methods of local and regional anesthesia, or who, still confusing the imperfect and dangerous methods of the past with the safe and efficient methods of the present, still doubt and cling to general narcosis as the only means of abolishing pain in their operations." Others who use cocain in minor operations are incredulous about its use in major surgery. If space permitted we could readily refer to papers by representative surgeons of this country and Europe, some of them reporting hundreds of major surgical operations, including operations on the appendix, gallbladder, and stomach. Individual surgeons in this country have not been behind the representative surgeons of Europe in introducing local anesthesia into major operations. This is not strange when we remember that the first clinical demonstrations of the value of cocain by the subcutaneous infiltration method were made by American investigators. Halsted, as early as 1884, introduced this method, and the papers of Corning in 1885, 1888, and 1894 antedated the work of all the early European investigators. The greatest advances of recent years have been in the injection of nerve trunks for regional anesthesia in the area supplied by those nerves, as used by Crile; the use of very dilute solutions, thus obviating the dangers of poisoning, the result of Schleich's efforts; the massive infiltration method of Matas; and possibly to this should be added the introduction of less poisonous drugs. Matas¹ gives practically everything of historic importance, and with regard to technic, up to the date of his publication, and very little has been added since that date. A valuable suggestion, which we believe has not been generally adopted, is that of Elsberg,² who first suggested, so far as we know, the addition of adrenalin to solutions to prolong their effects and to prevent hemorrhage during the operation under local anesthesia. It has long been known that if a part could be rendered bloodless by the use of a tourniquet that anesthesia could be considerably prolonged, but we are not aware Elsberg's suggestion has come into very general use. Barker³ has apparently hit upon this method independently, and he reports 30 major operations, including several radical cures of hernia, by this method. Elsberg recommended a strength of 1 part adrenalin to 20,000, but Barker finds it satisfactory in a strength of 1 to 100,000, using eucain instead of cocain. Already over a third the operations in Mikulicz's clinic are done under local anesthesia, and, because of its greater safety; the freedom from the discomforts which follow general anesthesia; and the dread of losing consciousness; we are confident that sooner or later, probably in the hands of the rising generation of surgeons, local anesthesia will largely supplant general anesthesia. Anything which can be done to hasten that day will be of almost as great advantage to the operating surgeon as to the patient who has to undergo operation.

REVIEW OF LITERATURE

Arterial-venous Traumatic Aneurysms.—E. von Bergmann⁴ says the most weighty hypothesis concerning their

formation is, a small opening at the point of ingress and egress, a long bullet path which strikes the artery obliquely, and a rapid healing of the wound. He believes the opening in the artery and vein of the case he reports was only 1 mm. or 2 mm. in diameter. In v. Bergmann's opinion the primary and the secondary hemorrhages indicate that the injury to both vessels was simultaneous. The secondary hemorrhage ceased when the patient straightened his leg which either kinked or stretched the bullet path. V. Bergmann ligated the artery and the vein above and below and resected the aneurysmal sac. [J.F.]

The Limit of Safety in Multiple Operations.—A. Vander Veer¹ discusses this question at some length, referring particularly to cases that present multiple surgical symptoms instead of accident cases. A general principle to be remembered is that the nearer the heart and brain are approached, the more serious the cases are likely to be. Among the conditions requiring careful consideration are those where cancer of the breast and rapidly growing cystic fibroid goiter are combined, or where there are multiple fibroids of the uterus causing pressure symptoms, associated with signs of unilateral pyelitis and a cystic tumor of the breast. A personal case similar to the latter ended in recovery of the patient after the abdominal tumor and the breast and lymphatic glands had been removed at the same time, but the impression gained was that the favorable result was due only to the fact that the patient was an exceptionally sanguine and rebounding subject for convalescence. Vander Veer speaks of the astonishing list of operations sometimes done upon the female genitalia, consisting of dilation, curetment, repair of bilateral laceration of cervix, cystocele, rectocele, and lacerated perineum, and then followed by opening the abdomen, removal of an ovary, the appendix, if diseased, and finally, fixation of the uterus. It would be of great importance to the profession to be informed of the real mortality brought about by so extensive and continuous operations. In conclusion, Vander Veer states his belief that extreme multiple operations, deliberately planned, should not be encouraged. [A.G.E.]

True Cysts of the Long Bones.—Carl Beck² reports a case in which the diagnosis was made by the röntgen rays. Operation proved the correctness of this view. He states that these cysts are closely related to rachitis. He looks upon them as a product of inflammatory atrophy. [A.B.C.]

General Anesthesia by Ethyl Chlorid.—M. Herrero y Zavala³ considers it effective, giving tests on animals and a case in point as confirmatory. Its use at present is limited to operations of brevity in more or less superficial regions. But reports from Europe tend to prove its advantages. Half a minute after inhaling its fumes, diluted with water and given on a compress and diffused with a proportion of air, the patient, a boy of 20, developed enough analgesia to allow the operation, one on account of trauma of the lumbar muscles. Immediately after which the patient was able to walk and gave an interesting account of his feelings. Sensibility is lost before consciousness. Repeated inhalations are needed to obscure the latter, but the former persists throughout. A meal was enjoyed one hour following the operation. [T.H.E.]

Acute Primary Typhlitis.—Jordan,⁴ after reviewing the literature and the opinions of the most distinguished men on the subject, says evidence of the occurrence of acute simple typhlitis has not yet been produced. In a case he found the anterior wall of the cecum .5 cm. thick; the mucous membrane presented several polypoid excrescences, but microscopically there were no evidences of tubercles. The mucosa and submucosa were abundantly, the muscularis and the serosa less abundantly infiltrated with lymphoid cells, among which he found staphylococci. Jordan concludes that the inflammation began in the mucous membrane as a result of pressure or irritation of stagnating fecal masses or other foreign bodies, the effects of which allowed the ingress of bacteria. [J.F.]

Postoperative Benign Icterus.—R. de Bovis⁵ reports 2 cases. One in a man of 20, following an easy operation for

⁵ La Semaine Médicale, September 9, 1903.

inguinal hernia; the other following instrumental delivery of a dead fetus in a multipara. In both cases the icterus was of few days' duration and constitutional symptoms were slight or entirely absent. De Bovis concludes, that in addition to surgical icterus due to pyemia, contusion or wound of the liver, diathesis, or intoxication by chloroform, in all of which prognosis is usually grave, there may be a fleeting icterus that is entirely benign. The cause of this last variety is simple biliary retention, of which the principal factor is doubtless a reflex originating in the abdominal region. A certain degree of hepatic predisposition or of intoxication favors its appearance. [A.G.E.]

Anastomosis of the Vas Deferens with Resection of the Epididymis.—Bogoljuboff¹ did 20 operations on 10 animals. His operations consisted of 2 types; in one he performed a total resection of the epididymis and implanted the vas deferens into the testicle in the region of the rete testis; the other consisted of resection of the lower half of the epididymis and implantation of the vas deferens into the substance of the upper half of the epididymis. At intervals varying from 31 days to 105 days after operation, he castrated the animals and injected colored gelatin through the vas deferens into the testicles, which he examined microscopically. In two of the first type and four of the second type the vas anastomosed with a patulous canal. In four the canals were only slightly patulous. He believes his results would have been more satisfactory had so many not suppurred. [A.B.C.]

Surgical Interference for Pyloric Stenosis.—Giuseppe Avanzino² reports 2 such operations. In 1 case, resulting from ingestion of nitric acid, a pyloroplasty did not result effectively, and the patient, a boy of 18, died after 8 days. The operation was not done until 6 weeks after the fatal attempt. The second case, one of gastroenterostomy, proved successful. The patient, a mechanic of 27, following a family tendency, attempted suicide with sulfuric acid. At first given medical aid, with the onset of pyloric stenosis, improvement disappeared and weight was lost rapidly. The operation after 3 months performed by Nassi has resulted in cure. [T.H.E.]

Perforation of the Intestine in Typhoid Fever of Children.—C. A. Elsberg³ states, that according to Keen's paper published in 1900, that 159 cases of perforation in typhoid fever had been operated upon, showed 23% recoveries. The writer in March, 1903, found 131 additional cases, making 289 in all, which showed 26% recoveries. Twenty-five of these patients were under 15 years of age. The 25 children operated upon showed a mortality of only 36%, while 264 adults operated upon showed a mortality of 77%. The chances, therefore, among children is more than 2 to 1 in their favor. He prefers chloroform to ether in local anesthesia. The author states it may be many years before there is much improvement in the surgical technic in treating these cases, but early recognition and improved diagnosis ought to reduce the mortality materially. His conclusions are that perforation of the intestines in the course of typhoid fever is very nearly as frequent in children between the ages of 6 and 15 years as in adults; that the symptoms do not differ essentially from those of adults; that, however, recovery may in exceptional cases take place without operation, the treatment should be surgical, and as soon as the diagnosis has been made, and that prognosis after operation is more than twice as good in children as in adults. A very early operative interference offers the best chances of recovery. A table of 25 cases of laparotomies in children for this affection is appended. [A.B.C.]

Total Extirpation of the Hypertrophied Prostate.—O. Zuckerkandl⁴ did perineal prostatectomy on 8 patients, ranging from 62 to 74 years of age. Chronic urine intoxication, hemorrhage from the prostate, narrowing of the urethra, and in 3 cases, stone in the bladder, were the aggravating symptoms. In all the cases there was an infection of the bladder. Cystitis and pyelitis were not looked upon as contraindications—in fact, in 1 case a pyelonephritis was helped. The wound heals in about 4 weeks, although in exceptional cases this is extended to 7 or 8 weeks. In 2 cases a fistula persisted. Epididymitis followed during the course of healing in 3 cases. The result of

operation in all cases was favorable, and spontaneous urination persisted afterward. The stream was strong, and of good character, and in all cases there was an absence of residual urine. The innervation of the sphincters and detrusors returned to the normal. In 1 case there was some transient incontinence which was relieved by faradism, and in another case there was an occasional loss of a drop of urine. The results of the retention of urine disappeared with the restoration of normal micturition. The operation is contraindicated in cases of chronic complete retention which becomes complete on account of local symptoms, or when the catheter is only passed with great difficulty, and finally, when the condition is complicated by the presence of a stone. The histories of the cases are given in detail. He also reports 2 cases of suprapubic prostatectomy, both of which were fatal. [J.H.W.R.]

Inflammation of Meckel's Diverticulum with Obstruction of the Intestinal Lumen.—Rebentisch¹ states that 11 such cases have been reported in literature. Denecke collected nine; Zimmerman reported one. Three of the eleven were identified at autopsy; eight were operated upon. In 1 case only could an artificial anus be made; another came to operation only after the formation of an abscess in the abdominal wall, and a fistula had occurred. Of the remaining 6 cases at least three were cured, and possibly a fourth. In Rebentisch's case there was empyema of the diverticulum and obstruction of the intestinal lumen, necessitating the removal of 28 cm. of the ileum. He believes the condition is analogous to appendicitis and calls it "diverticulitis." [A.B.C.]

Treatment of Congenital Phimosis.—W. M. Rojansky² makes a plea against the indiscriminate employment of the knife in this condition. Circumcision, excision, incision, are all in use, while the same results can be obtained by bloodless treatment. His own method is outlined as follows: The mother is instructed to irrigate the preputial sac with a weak antiseptic, preferably a 2% solution of boric acid. In the presence of congestion or irritation, lead-water may be substituted for the above. These injections are given 2 to 3 times daily by means of an ordinary rubber ball-syringe holding a half ounce of fluid. The tip is inserted into the sac and the contents slowly forced out, distending the prepuce. After 2 to 3 weeks of such treatment the prepuce can be retracted almost behind the glans. At this stage a dull probe is introduced between glans and prepuce, and the remaining adhesions are gently loosened. The cure is now complete, and may be made permanent by continuing the irrigations for some time longer, in order to prevent the formation of fresh adhesions. [L.J.]

Hyperalgesic Zones in Bullet Wounds of the Head.—Wilms³ reports 4 cases of bullet wounds of the head, in all of which a zone of hyperalgesia occurred on the neck and back of the head. There was no disturbance of sensibility in the affected region. There was no doubt that the hyperalgesia was of central origin. The pains were symmetric on both sides of the body, and of equal intensity. The upper limits of the hyperalgesic zone corresponded with the boundary of the sensory zone of the trigeminus nerve. The extent of the zone did not correspond with the distribution of any peripheral nerve. One patient died, and 3 recovered, the pains disappearing in 8 to 10 days. The form of the hyperalgesic zone pointed to a lesion of a spinal cord segment. The symptom is explained as follows: The bullet produced a lesion of the sympathetic in the neighborhood of the cavernous sinus. The irritation was conveyed along the sympathetic to the communicating segment of the cervical spinal cord. There the irritation affected the centers of sensory nerves, the pain being referred to the zone of skin corresponding to the affected segment of the cord. [B.K.]

The Influence of the Vitality of the Tissue in Local Anesthesia.—H. Braun⁴ says there can be no doubt that the amount of blood in an area, or better the vigor of its metabolism and the vitality of its tissues, influences the intensity, the extent and the duration of the local anesthetic effects at that point. Each disturbance of resorption, each injury to metabolism is followed by an increased effect (local) of the substance

used. Such changes are produced by checking the blood stream through mechanical means by the application of extreme cold and by the local use of adrenalin to the part. He has never seen any bad effects follow the use of a combined solution of cocain and adrenalin. If he intends to inject a 1% solution of cocain in small amounts he adds to this 3 drops of a 1-1,000 solution of adrenalin. On the other hand, if he intends to inject a .1% to .5% solution of cocain he adds 3 drops of the adrenalin solution to 5 cm. or 10 cm. instead of 1 cm. of the cocain solution. [J.F.]

Chronic Gonorrheal Prostatitis.—L. Waelsh¹ examined the secretion of the prostate in 200 cases of gonorrhea, and found it normal in 38 cases, or 19%; the secretion contained few or no leukocytes. In 28 of these 38 cases, the infection was limited to the anterior urethra; of the 172 cases of posterior urethritis, 162, or 94%, had prostatitis as a complication; only 11 of these cases presented prostaticorrhea as the leading symptom. The treatment is unsatisfactory; that giving most satisfaction being manual massage by way of the rectum, followed by instillations into the posterior urethra. Great care is necessary, however, to prevent bad results. He reports a case in which very grave neurasthenia and prostatitis followed the treatment, disabling the patient for months. [E.L.]

Inflammatory Strictures of the Large Intestines.—J. Koch² divides simple inflammatory stricture into those affecting all the strictures of the intestine except the mucosa, and those in which the mucosa plays the most important part. The first variety results from false diverticulums of the intestine; the second is rare. He quotes Sudsuki's 3 causative factors which he believes are connected: (1) Lessened resistance of the loose fibrous tissue; (2) presence of fat in the vessel bifurcations and pressure of fecal material and gas; (3) muscular action. The retention of fecal material in the diverticulums produces inflammatory conditions and abscesses; these result in an overproduction of fibrous tissue, cicatrices, and finally strictures are formed. He believes the strictures occur in the sigmoid more frequently, owing to the fecal accumulation at this point, especially where there is a tendency to obstipation. When the condition is of long standing, it may occasion morbid processes of neighboring organs; in his case there was a secondary cystitis. [A.B.C.]

Inflammation of an Intestinal Diverticulum.—E. Dineur³ reports a case of this character in a man of 57 who, after drinking 2 glasses of beer, was seized with colic. The abdomen became tympanitic, especially around the umbilicus. There was no tumor demonstrable. The lungs and heart were normal. Fecal vomiting began on the second day and continued till the last. On the third day of the disease he had a liquid movement from the bowels accompanied by gas, and died on the following day. The autopsy revealed the presence of a diverticulum 30 cm. (12 in.) from the ileocecal valve, measuring 9 cm. (3½ in.) in length and 5 cm. (2 in.) in diameter. It was cylindric and perpendicular to the intestinal canal; of the same structure as the intestine, and contained a brown fetid liquid which contained coli bacilli. The bacilli were very toxic to guineapigs. Dineur believes that the possibility of inflammation of an intestinal diverticulum should be thought of in all cases of gross clinical signs of acute intoxication resulting from appendicitis, intestinal occlusion, or strangulated hernia, and that an operation in these cases should not be deferred for a moment. [J.H.W.R.]

The Surgical Importance of the Elasticity of Muscles.—Tillmann⁴ says with normal bones and ligaments a disturbance in their equilibrium can occur only when the equilibrium security of the muscles is no longer normal. After overcoming the muscles, the ligaments must be damaged before the bones take part in the alterations. The elasticity is determinative in securing the muscle equilibrium. Security of the joints is dependent upon the weight. Changes in these factors produce pathologic alterations in the equilibrium relations. The elasticity alone makes it possible to keep the muscles constantly stretched so that no time is lost in contraction. It prevents

tearing in sudden contractions. From Blix's experiments he concludes that overtaxing stretched muscles produces alterations in the length of the muscle for some time. The permanent lengthening is greater in frequent taxing than in the taxing where the same amount of force is exerted but at greater intervals. Tillmann traces many deformities to the overtaxing of the muscle elasticity. It is seen in scoliosis or in alterations in the curvature of the spine, due to incorrect position, as in school children. In bending over their desks the musculature of the back is kept upon the stretch for hours at a time, with a resulting degeneration of these muscles. On the other hand, the muscles of the concave portion of the arch become relaxed and shortened, so that there results a disturbance in the muscle equilibrium and antagonism of the musculature in question, with an alteration in the spinal column. Upon the same principles, he attributes the occurrence of genu valgum and deformities of the feet. [J.F.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

The Plastic Closing of Vesicovaginal Fistulas by Means of the Cervix Uteri.—Küstner has shown that by the plastic use of the supravaginal portion to close a vesicovaginal fistula certain results can be secured. This principle has been previously employed by Wolkowitsch, but was simplified and brought into more general use by Küstner. H. Thomson¹ reports 3 cases in which he used this procedure with satisfactory results, and was impressed with its mechanical power. There remains no doubt that through the use of the collum uteri for the closing of a vesicovaginal fistula, an extensive surface and firm support are furnished, and the chance of a permanent cure increased. Also, the conditions after the operation, are normal, and the possibility of cohabitation, pregnancy, and delivery preserved. The broad wound surface he sutures with deep silkwormgut sutures. Lastly, catgut sutures guarantee permanent cure and exclude later complications on the part of the bladder. After the operation the catheter is permitted to remain 8 days to 10 days, and the sutures removed at the end of 2 weeks. Small fistulas may be remedied with a simpler process, but for large fistulas the plastic use of the collum uteri is Thomson's choice. [W.K.]

The Kidney in Pregnancy.—R. W. Stewart² bases his study upon the examinations made of urine voided by 85 women at various periods of gestation. If a rule of treatment should be formulated from a study of these cases, it would be: Symptomatic procedures when albumin occurs without casts or other symptoms; accouchement force when casts, red cells and diminution in the quantity of urine accompany the albumin, unless these signs show marked improvement in 24 hours. He advises the termination of pregnancy if the albumin should continue to increase in quantity and the daily quantity of urine be at the same time greatly diminished, even if there are no casts or other signs of nephritis. [F.C.H.]

Contemporaneous Extrauterine and Intrauterine Pregnancy.—Ernst Meyer³ reports 2 cases of this kind, which show that clinical appearances in combined extrauterine and intrauterine gestation are very variable and the diagnosis difficult to determine. It will be easiest when the appearance of interrupted ectopic gestation is accompanied by the expulsion of the intrauterine fetus. At an earlier stage it may be difficult to distinguish between the decidually changed uterus of ectopic gestation and a pregnant uterus, and in many cases the true condition can be determined only by microscopic examination of the uterine contents. [W.K.]

Observations on Puerperal Septic Infection.—C. Jewett⁴ compares the number of puerperal deaths with the total deaths from all causes as shown by the records of the Brooklyn Health Department for the last 32 years. The table gives evidence of material reduction in the mortality during recent years.

³ Zentralblatt für Gynäkologie, November 14, 1903.

⁴ Brooklyn Medical Journal, January, 1904.

Though this is largely due to the diminished deathrate in hospitals, Jewett says that the showing of physicians in private practice is not so bad as is usually pictured. Results in general practice will improve when physicians look solely to their fingers and instruments as the carriers of infection. Needless internal manipulation during delivery is too common. A custom which may favor infection is the rigid maintenance of the recumbent posture after labor. In normal cases and many others the patient may be allowed to assume a sitting posture for bowel and bladder evacuations. The indiscriminate use of the curet is one of the most frequent causes of death in cases of postpartal infection. Fingers and uterine dressing forceps had better replace it. To some extent the same objections apply to the use of the douche. Generally it should be used but once and then as a part of the primary cleansing. [A.G.E.]

A Modified Method of Producing Female Sterility Employed on Account of Rare Diseases.—P. Rissmann¹ describes a method of sterilization used by him in the case of a woman afflicted with convulsions, either of epileptic or hysteric origin. He makes a posterior vaginal incision and the normal anteverted uterus with its posterior surface is drawn down into the vagina so that the fundus also lies near the vulva. The Douglas sac is opened with a low incision beginning at the portio. Through this, catgut sutures are introduced. Sutures are placed in the posterior uterine wall, and with bullet forceps the uterus is turned back so that the fundus and both tubes are perceptible. Then the uterine portion of both tubes was excised. After exact suturing of the wound, the uterus was replaced and the incision in the vaginal vault closed. The patient whose case is reported left the hospital 18 days after the operation. He believes that sterilization was indicated from the great frequency and violence of the convulsions and the general condition of the patient. [W.K.]

Objections to the Vaginal Route in the Treatment of Ectopic Gestation.—J. W. Boyée² gives the following reasons for preferring the abdominal route to the vaginal in every case of operation for tubal pregnancy. The field of hemorrhage can be more quickly reached by this route, taking into consideration the relative amount of time consumed in cleansing the 2 routes under anesthesia; the condition can be more readily treated, and the ligation of bloodvessels more readily and certainly performed; the danger from secondary hemorrhage in ectopic pregnancy is markedly less when ligation is practised than when removal of blood clots alone is done; any other important pathologic lesion requiring attention in suitable cases may be treated at the same sitting; the shock as a rule will be less than if the vaginal and abdominal incision are both made; the tube can be more readily removed than by the vaginal route; the abdominal route is applicable to all stages of the pregnancy, while the vaginal cannot be employed for the later stages; the vaginal incision has no place in the treatment of unruptured tubal pregnancy, while the abdominal incision is the route *par excellence*. [F.C.H.]

The Artificial Turning of the Fetus in Cranial Presentation.—Gottschalk³ in cases of forehead presentation advocates the correction of the position by turning the fetus before delivery. To accomplish this he has used a combined procedure, the direct influence upon the occiput from within and rotation of the shoulders externally. But in the last 4 years he has sought to effect the whole procedure by using the hands externally, and with such good results that he recommends this method in his textbook. It is best performed as soon as possible after the rupture of the membranes and always in the interval of labor pains. [W.K.]

Ascending Renal Infection.—J. A. Sampson⁴ speaks of ascending renal infection with special reference to the reflux of urine from the bladder into the ureters as an etiologic factor in its causation and maintenance. This question was made prominent by the death of several patients, from ascending renal infection, subsequent to resection of the ureters in radical operations for cancer of the cervix. The anatomy and physiology

of the ureters and bladder and the etiologic factors in cystitis and ascending renal infection have been studied in man and in dogs by Sampson, and, in part, the following conclusions have been reached: Under normal conditions it is impossible for fluid to pass from the bladder into the ureters; organisms may be conveyed from the bladder to the kidney through the following channels: (1) The general circulation; (2) the vesico-uteroovarian anastomoses; (3) the bloodvessels of the ureter; (4) the lymphatics; (5) the lumen of the ureter. Several ways by which the latter process may be accomplished are given, one of them being reflux of urine. The most important point enunciated is that the reflux of urine from the bladder into the ureters may be considered an etiologic factor in the causation and maintenance of renal infection only when the intravesical portion of the ureter is diseased, thus impairing its function, or when some ureteral abnormality exists. Lowered local and general resistance must be considered. [A.G.E.]

Adjunct to Uterine Irrigation in Puerperal Fever.—D. Watson¹ thinks that uterine irrigation is most likely to be useful in the early stages of puerperal fever. To avoid the dangers which may arise from leaving the uterus wet, thus dissolving the toxins and promoting their absorption, or by assisting the growth of microorganisms, every trace of water should be removed from the uterus. In order to do this, Watson uses this method: After expressing as much of the douche solution as can be got rid of in this way, he injects into the cavity of the uterus 1 oz. of glycerin, containing 3% of formalin. This solution is quite innocuous and unirritating, and in addition to its powerful antiseptic action, it removes all water from the uterus and its use prevents any rise of temperature following the douche. To inject the glycerin, all that is required is a glass syringe of 1 oz. capacity, with a small piece of rubber tubing attached to its nozzle for connection with the catheter, which has meanwhile been left in the uterus. He cites 2 cases, showing the beneficial effects of this method. [W.K.]

Cesarean Section on Account of Eclampsia during Pregnancy.—H. Saft² reports the case of a woman who was brought to his clinic in convulsions; she had edema for a good part of her pregnancy and was blind for several days prior to the onset of convulsions. The urine contained a 3-moist layer of albumin. He performed a cesarean section through the vagina. The patient recovered after passing through some days of convulsions and maniacal attacks. The author lauds the ease of the operation, the rapidity with which the child can be removed, and the absence of operative danger to the mother in performing cesarean section through this route. [E.L.]

Hebotomy.—Gustav Arndt³ reports a case of hebotomy, stating that only 2 methods of procedure were in question, cesarean section, and splitting of the pelvic rim. Because of the high temperature, cesarean section was rejected and the extramedian section of the pelvis according to Gigli was performed, with the delivery of a living child and satisfactory recovery of the mother without fever. In this extramedian cutting through of the pelvis, there was no laceration of the vagina nor any injuries to bladder or urethra. The bleeding was moderate and readily controlled by tampons. Arndt believes that this method has decided advantages over symphysiotomy and will have a permanent place in obstetric surgery. [W.K.]

Accouchement Force.—R. L. Dickinson⁴ discusses manual dilation and bag dilation. He concludes as follows: For induction in the latter months, and for inertia during labor (where other causes are eliminated, such as exhaustion, overdistension, and malposition of passage or passenger), the bag comes first, then the hand, and the forceps finish their work for placenta prævia, the balloon for the narrow cervix that bleeds, when the head will not plug it, and for the bad cases version, since the thigh is the surest tampon; for brisk hemorrhage of detachment of a normally located placenta, the greatest speed, to wit, manual or metal dilation; for the rigid cervix of the early months, for the unyielding girdle of the elderly primipara, for the gristle like hardness of eclampsia, the powerful

⁴ The American Journal of Obstetrics, July, 1903.

Bossi instrument is a great boon, and none of its imitators approaches it. [F.C.H.]

Rupture of Vagina and Muscular Pelvic Floor as Cause for Genital Prolapse.—Schalz¹ believes that the perineum is only of very secondary importance as a means of closing the pelvic cavity, that the real pelvic support is higher up, and while it remains intact, laceration of the perineum will not cause prolapse. Care of the perineum should not, therefore, divert the attention from more important points. Prolapse is, however, often due to rupture of the vagina caused by too early and too strong pressure during labor, especially the senseless pressure from the use of the bandage or girdle. This rupture of vagina may also be caused by the use of forceps, by the early extraction of the breech and even by pressure of feces. Therefore, we should always, when possible, protect a primipara from breech presentation by external version during pregnancy. [W.K.]

Bladder Changes Cystoscopically Evident in Uterine Carcinoma.—W. Hirt and R. Sticher² give in detail the result of careful cystoscopic examination of the bladder in patients suffering from uterine carcinoma. They found in the mucous membrane of the bladder, especially in the trigonum between the internal orifice of the urethra and of the ureters, peculiar accumulations of epithelial cells, some conical, some spheric, and others of irregular forms. These masses of cells varied according to the condition of the carcinomatous growth; and the writers are of the opinion that the character of these changes in the bladder as shown by the cystoscope may determine whether the cancer is operable or inoperable. Several cases are cited to sustain this theory. [W.K.]

Cervical Incisions in Labor.—R. W. Holmes³ discusses the anatomic considerations, indications, contraindications, dangers, the operation and technic of cervical incisions in labor. He concludes as follows: Effacement of the cervix is an indispensable prerequisite to the use of incisions, for this reason incisions are especially applicable to primiparas, and often are contraindicated in multiparas; manual dilation preliminary to incisions does not secure the best cervical condition for incisions; incisions are always potentially dangerous, particularly to infection, hemorrhage and extensive lacerations beyond the vaginal vault; the use of incisions demand an obstetric armamentarium, assistants, and a definite experience in obstetric procedures; the details of the technic may be modified to suit the taste of the operator; the minimum number of incisions to meet the exigencies of the case should be made; oblique incisions may prove to be more advantageous as regards the after effects than the usual quadrant cuts; in the absence of hemorrhage or accessory lacerations it is a mooted question whether the incisions should be sutured or not. Immediate delivery should follow the incisions. [F.C.H.]

Eclampsia and Morphin.—W. Boxer Mayne⁴ reports 2 cases of eclampsia successfully treated with morphin. A woman, aged 22 in the fifth month of pregnancy was suddenly seized with an eclamptic fit. When he reached her she had emerged from the subsequent comatose condition, and was vomiting freely, but unable to recognize any one about her. He gave a hypodermic injection of $\frac{1}{4}$ gr. of morphin, and 2 m. of croton oil, and had her wrapped in blankets. There was no recurrence of the convulsions; she miscarried during the night, and recovery was uneventful. In the second case the convulsion developed suddenly after delivery; morphin was given with $\frac{1}{16}$ gr. of strychnin, and then the patient was wrapped in hot blankets. Recovery was uneventful. [W.K.]

Six Cases of Cesarean Section, with Favorable Results.—A. v. Valenta⁵ reports 6 cases of cesarean section for contracted pelvis and osteomalacia with the delivery of living children and the recovery of the patients. The results in the 4 cases of osteomalacia were considered very good, since the women, who could not move about for weeks before the operation, could walk without pain when they left the hospital. [W.K.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

The Treatment of Pulmonary Tuberculosis Outside of Sanatoriums.—While the benefit of properly conducted sanatoriums cannot be denied, there are often cases in which for monetary and other reasons this method of treatment is inapplicable. Minor¹ points out that it is a great mistake to suppose that the hygienic treatment of the tuberculous cannot be carried out except in special institutions. The treatment under these circumstances necessitates not only the most watchful care of the physician, but insistence on absolute obedience to orders. It is necessary in order to get good results that the patient should live in a house with sunny exposure, and as far as possible from congested centers. An absolutely necessary adjunct is a wide veranda or yard well protected from the winds, and if possible, with a southern exposure. The utmost attention must be paid to the diet, to see that the food is of sufficient variety, as well as prepared so that it will be easily digested and tempt, so far as possible, the appetite. Beside 3 meals a day, Minor gives on waking, at 11 and at 4 o'clock and at bed-time, a luncheon, consisting of milk, crackers with a raw egg, or some similar easily-digested food. In order to get certain adherence to directions, the physician must study his patient's character, be absolutely frank concerning his condition, and explain reasons for the various orders. The orders should be written and cover every detail of the day's life; to insure these orders being carried out, the patient should keep a record book, not only of his temperature and pulse and general feeling, but the exact amount of time spent out of doors, the amount and nature of his exercises, the condition of his digestion, etc. Minor does not believe as some, that the study of his case by the patient has a harmful and depressing effect, but thinks that it is necessary in order that the patient shall help so far as possible in his treatment. He begins treatment with a week or two of absolute rest, preferably in a reclining chair out of doors, with frequent observations of the temperature. After this period, if the temperature has not exceeded 99.5°, the patient is allowed to begin moderate exercise. The exercise begins with a walk on the level of from 2 to 5 minutes, which is increased 1 to 5 minutes daily if there is no sense of fatigue or rise of temperature. In order to prevent the effect of ennui, the physician should see that his patient has such amusements as are permissible, according to the severity of his case. The day's routine Minor uses is as follows: An hour before rising a servant closes the window, and if the weather is cold, heats the room to 55° to 65°. The patient takes a glass of warm milk before rising, and then a cool salt bath, lasting but a few seconds, followed by a brisk rub. After breakfast he spends the morning in a reclining chair, excepting the time devoted to exercise. Nourishment is taken at 11 o'clock. In the afternoon the routine is the same, with the exception that in the earliest stages of the treatment there is no exercise. If there is artificial light the evening may be spent on the veranda; if there is not, it is better spent in the patient's bed-room rather than in a sitting-room, because the ventilation can be more easily controlled. [H.C.W.]

Melancholia.—Dercum says of thyroid extract in the treatment of cases of melancholia of prolonged course, that in a number of instances it appears to act as a cerebral stimulant. However, its action is inconstant, and if given in decided doses, it will add to the nervousness from which the patient is already suffering. With agitated patients it should not be used at all. The author uses it only occasionally in very prolonged cases and for brief periods, during waves of increased depression. On the whole, its action is disappointing.—[*"System Physiologic Therapeutics,"* Vol. viii.]

Petroleum Poisoning.—Aronheim² describes a case of poisoning in a 2½ year old boy, poisoned by drinking 120 gm., or about 4 ounces of petroleum. The symptoms were uncon-

acclousness, cyanosis, cold moist skin, pulse small and very rapid, pupils dilated, and some bubbling rales in the lower part of the lung. The treatment consisted in hypodermic use of camphorated oil, external heat, and a mixture containing sodium bicarbonate and methyl atropin bromid. Later the child vomited blood-stained material with a strong petroleum odor, and passed a large quantity of urine free from albumin and smelling strongly of petroleum. In 2 days the patient had completely recovered. [H.C.W.]

Toxialimentary Dyspnea in Tuberculous Patients.—H. Huchard¹ states that the presence of dyspnea in tuberculous patients does not prove that it is of pulmonary origin. It may be the result of insufficient elimination by the kidneys. He reports 2 cases: The first in a patient suffering from advanced tuberculosis with the usual symptoms of this disease with very marked dyspnea, which was not lessened by repose. The severity of this dyspnea was far in excess of that usually seen in these cases. It was diagnosed as belonging to the group of toxialimentary dyspnea of arteriosclerosis. The patient was ordered an exclusive milk diet for 4 days. To this was added 1.3 gm. (20 gr.) of theobromin. The result confirmed the diagnosis; the patient passed large quantities of urine; at the same time the oppression disappeared as by magic and the dyspnea markedly decreased. The second case was similar, excepting that the patient was not so far advanced in tuberculosis, but symptoms of arteriosclerosis were also present. A milk diet with theobromin produced the same good result. [L.F.A.]

The Cure of Angioma by Means of Electrolysis.—Arienzo² has had good results in the treatment of angioma by the use of currents of high frequency, and by using an especial electrode he has avoided the occurrence of hemorrhage, which has interfered with the use of electricity in these conditions. A small angioma was treated with only the spark of the current at high frequency and for not more than 2 or 3 minutes, on alternate days. In cases of very large growths, electrolysis by the bipolar method (the current from 20 ma. to 40 ma.) followed by the use of the spark, [was employed. It required several months for complete cure of the condition. He believes that the currents act by producing a coagulation of the blood in the neighboring capillaries leading to atrophy of the growth. [H.C.W.]

The Mode of Action of Ichthyol in Pulmonary Tuberculosis.—It is inconceivable, according to Burnett,³ that ichthyol may do good in pulmonary tuberculosis, either by an antiseptic action, effect upon nutrition, or by some local alternative effect. It is too feeble an antiseptic to render it at all probable that it does any good this way, and there seems to be no diminution in the number of tubercle bacilli under its influence. Although it seems to have a beneficial action as a conservator of proteids, its nutritive influence is not powerful enough to make it of benefit in this manner. Burnett believes that it acts by combating the inflammation in the lungs in the same way that it combats the inflammatory process when applied locally. [H.C.W.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended January 22, 1904:

Changes in the Medical Corps of the U. S. Army for the week ended January 23, 1904:

WHITE, J. SAMUEL, contract surgeon, is relieved from duty at Fort Yellowstone and will take station at Fort Snelling, Minn.

The following named officers will report to Major William H. Arthur, surgeon, president of the examining board at the Army Medical Museum Building, D. C., on March 14, for examination for promotion: Captains Champe C. McCulloch, Jr., Frederick P. Reynolds, Robert S. Woodson, Harry M. Hallock, George J. Newgarden, Paul F. Straub, Alexander N. Stark, Charles Lynch, John S. Kulp, assistant surgeons.

STEWART, LYELL R., sergeant first class, now at the Army General Hospital, Presidio, will proceed to Fort Duchesne for duty.

HAUGHEY, PATRICK, sergeant first class, depot of recruits and casuals, Fort McDowell, will report to the commanding officer, who will send him to Manila, P. I., on the government transport sailing from San Francisco, February 1.

KNAPP, GUSTAV, sergeant first class, now on temporary duty at Ord Barracks, Monterey, Cal., will proceed to Fort McDowell.

GREGORY, VERDO B., contract surgeon, now at Janesville, Wis., will proceed to San Francisco, Cal., for transportation to the Philippine Islands.

MILLS, FREDERICK H., contract surgeon, now at South Dayton, N. Y., will proceed to San Francisco, Cal., for transportation to the Philippine Islands.

MACY, FRED S., contract surgeon, now on leave at Somerville, Mass., is relieved from further duty in the Philippine Division, and upon the expiration of said leave will proceed to Allegheny Arsenal, Pittsburg, Pa., for duty.

WOODSON, Captain ROBERT S., assistant surgeon, is granted leave for two months, from about February 1.

BAIRD, WM. T., contract surgeon, is granted leave for two months, from about February 1.

Changes in the Medical Corps of the U. S. Navy for the week ended January 23, 1904:

MOORE, A. M., surgeon, retired, detached from the Naval Recruiting Station, Chicago, and ordered home—January 16.

WILSON, G. B., surgeon, detached from the Wabash and ordered to the Naval Torpedo Station, Newport, and to additional duty in attendance upon naval and marine officers—January 16.

GARDNER, J. E., surgeon, ordered to the Wabash—January 16.

LUMSDEN, G. P., surgeon, detached from the Naval Torpedo Station and ordered to the Naval Recruiting and Marine Recruiting Stations, Chicago, Ill.—January 16.

WENTWORTH, A. R., surgeon, detached from the Albany and ordered to the Solace—January 20.

CRANDALL, R. P., surgeon, detached from the Wisconsin and ordered to the Oregon—January 20.

GUEST, M. S., passed assistant surgeon, detached from the Oregon and ordered to the Albany—January 20.

WEBB, U. R., assistant surgeon, detached from the Annapolis and ordered to the Naval Station, Cavite, P. I.—January 20.

BISHOP, L. W., assistant surgeon, detached from the Naval Hospital, Yokohama, Japan, and ordered to the Annapolis—January 20.

McCLANAHAN, R. K., assistant surgeon, ordered to the Asiatic Station via steamer sailing from San Francisco, February 1—January 20.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 6.

FEBRUARY 6, 1904.

\$5.00 YEARLY.

Venereal Disease and Military Life.—There has been a vast deal written in England during the last months concerning physical deterioration, army reform, etc., much of it too academic or theoretic in character. But there is one aspect of the problem which has not been brought out with sufficient clearness. The lay journals naturally shrink from the discussion, and with the medical journals it is an old and somewhat tiresome matter. Mr. A. C. Proffert has issued an illuminative monograph upon it which should command the serious attention not only of Englishmen, but in view of our own statistics and experience in this country, of the American people. Mr. Proffert says venereal diseases are the greatest of all causes of army inefficiency. In the English service the suspension of the contagious diseases act, and in our country the abolition of the canteen, have resulted in an enormous increase of venereal diseases, and both are the work of the same motives and agencies. These diseases in the English service at once increased by 50%, and they now account for about one-third of all the admissions to hospital. Of the whole army, they constituted in 1898, 46,761 and in the British troops in India, out of a total strength of 65,397 men, the "admissions for venereal" amounted to 24,286. These amazing figures do not tell the complete story, for there are hundreds of men annually admitted to military hospitals, suffering from such complaints as joint-affections, inflammation of various glands, various forms of rheumatism, diseases of the nervous system, etc., which, not being returned under the heading of venereal disease, are not included in the figures, but which nevertheless are the direct sequels of venereal disease. Again, it is well known that men whose constitutions have been weakened by venereal disease are specially liable to become attacked by those diseases which are endemic in tropical climates.

The Cost of Army Venereal Disease to the British Taxpayer.—Thus in the year 1898 there was in the British army a loss of 1,738,688 days' service. Six battalions were thus locked up in hospital every day of the year, and on the average almost half of the sickness in the Indian army was due to this preventable cause. At an average of five shillings a head per day the cost of these patients amounted to \$6,150 a day, or to \$2,244,750 per annum, or to the enormous sum of

\$6,734,250 for the three years. The cost of a private soldier of the infantry is \$262.56 a year; consequently, the sum annually expended on these preventable diseases would maintain about 8,500 healthy and efficient soldiers for one year. The cost in men is thus epitomized by Mr. Proffert:

On an average, 450 men are annually discharged from the army as being medically unfit for service owing to venereal disease. Thus a whole battalion of soldiers disappears every two years. If we take into account the number annually discharged as being medically unfit from the sequels of venereal disease, this number would probably be doubled, if not trebled. But this great waste of men and money is by no means all the price the country has to pay on account of the terrible state of affairs existing in the army. Since the introduction of the short service system thousands of young men annually return to civil life, many of them tainted with the poison of syphilis. It is conceivable that many of these, on settling down in civil life, will marry, the consequence of their marriage being that they infect innocent women with a loathsome and terrible disease, and bring children into the world so diseased that they will never be able to take their place in the battle of life. This aspect of the question, seriously affecting as it must do the classes of population from which our soldiers are drawn, becomes of national interest, and demands urgent consideration from all those who regard the health of the people as a matter of surpassing importance.*

Division of fees is a theme, as the musicians say, with almost an infinite number of variations. The noteworthy aspects of unblushing innocence and of publicity show that the profession is becoming divided on the question. If many physicians were not frankly accepting the bribes the advertisers would not send out circulars and letters plainly offering them. The only cure for the disease seems to be for those who will not accept, to place the ban of their disapproval upon the institutions or individuals who parade their degradation. We recently alluded to the offer of nurses to physicians of a percentage of the returns for recommending them to patients. There lie before us two letters, one from a young physician to a more famous one offering to pay a reasonable sum for being placed in charge of a patient to travel at home or abroad. Another letter from the proprietor of a sanitarium offers physicians the division of the spoils in the following terms:

We recognize the fact that physicians cannot place patients with us without sacrificing time, and incurring more or less

*The title of Mr. Proffert's pamphlet is "Army Inefficiency: Its Greatest Cause." It is published by Churchill, F. Blackiston's Son & Co. are the American selling agents.

expense or loss. This seems to me to very clearly entitle them to a liberal fee from us, which we cheerfully remit.

Drunkenness as a Cause of Crime.—In an English court, recently, of 47 cases, 39 were due to drink. Thus, 85% of the crime in that district was due to this cause. The justice, in commenting on this condition, said:

I have lately been brought face to face for weeks with the conduct of publicans in the carrying on of their business, which has resulted in the most heartbreaking crimes that it is possible to imagine. Husbands murdering their wives, wives their husbands, fathers their sons, friends their own best friends—all through the maddening influence of excessive drinking. Twelve murders, 18 attempts at murder, and woundings without number that were just as likely to have ended in murder so far as the conduct of the criminal was concerned, have been mine and my brother judges' daily fare for the last four weeks on one circuit, and in almost every case, as appeared in evidence, drink was the cause.

In view of such facts it seems the duty of physicians, both in private practice and in their public testimony as witnesses and experts, to set their faces resolutely against the all too prevalent tendency to view alcoholism solely as a disease. That intoxication is no excuse for crime has been the almost universal testimony of the Bench, but one of the greatest obstacles to making this view the unexceptional legal rule, comes from those so-called scientists who advocate the morbid doctrine that alcoholism is a disease, is insanity, etc. The only exception is in the case of murder, when it is possible to prove absence of "malice aforethought" by showing that the criminal was intoxicated. Even that excuse should be done away with because all an intending malefactor would have to do to be freed from the most heinous crime would be to get drunk before killing his victim.

Uncinariasis in Porto Rico.—Work on the subject of uncinariasis is taking on a very active color in Porto Rico. Despite some slight opposition on the part of some country doctors, the profession there seems to be greatly interested. The governor has called upon the Legislature for an appropriation of \$5,000 to "study and commence a campaign against the disease." The bill will probably pass, judging from the very general interest aroused in a disease that is consuming one-third at least of the inhabitants here. The Superior Board of Health is very active in forwarding these plans, and on the occasion of the second annual meeting of the Porto Rican Medical Association, Dr. Bailey K. Ashford was asked to deliver in Spanish a thesis on uncinariasis treating completely all sides of the question. The address was well received, and this body voted a commission to study the subject, and set the first Sunday in April as a day for an extraordinary meeting of all physicians on the island to compare their results. It is evident that there is a commendable spirit of progress among the profession of Porto Rico.

The Misfortune of a Colleague.—Every city practitioner should pay a visit once a year to some of his remote country brethren, whose practice is very different from his own. We may read of the experiences of the doctor in old times and under hard conditions, but

those practising today in poor and thinly settled communities can rival those of early days in heroism carried on for a life in the face of untoward circumstances. A subscriber sends us a letter, given in another column, which appeals to our sympathies. Concerning Dr. Remick, he says:

I hope some substantial aid can be obtained at once to help Dr. Remick. I know him personally, and have taken some of his long drives over the mountains in the summer with him. He has told me that in the winter he has often been two weeks without going to bed, sleeping in his sleigh while his wife or sister would drive. The fees he gets—fifty cents and seventy-five cents—are collected with difficulty, as the farmers handle little money. If it were not for the summer people, he could not live.

We have had the pleasure of sending a box containing about 50 good medical books to Dr. Remick's address. Dr. J. P. Torrey, of Andover, Mass., will answer the inquiries of correspondents concerning Dr. Remick.

Confirmations of Mendel's Law.—Biologic periodicals are likely to contain articles with regard to Mendel's law. Our readers will remember that over a year ago we called attention to this wonderful law founded on observation, not theory, in heredity, which had been discovered by an Austrian monk as the result of investigations conducted on the pea plants of his monastery garden. His work was utterly neglected for 35 years by all the biologists of the world, and finally rediscovered about four years ago almost simultaneously by some of the best biologic investigators in four different countries. At the present moment very few biologists are without interest in Mendel's law, and most of the zoologic laboratories and botanic gardens are conducting experiments in order to demonstrate its truth. Not long ago Professor Thomas Hunt Morgan, of Bryn Mawr, announced that recent observations seem to demonstrate the mathematic truth of Mendel's law, and he added, give the final *coup de grace* to the theory of natural selection. Within the last year Professor Wilson, the director of the zoologic laboratory of Columbia University, said that studies in cytology absolutely confirm this truth of Mendel's principles. Professor Castle, of Harvard, said that Mendel's law of heredity is doubtless one of the greatest discoveries in the study of biology and in the study of heredity, perhaps the greatest that was ever made. It is evident, then, that physicians, interested almost more than any other scientific observers in questions of heredity, must become familiar with Mendel's law and with the principles on which it is founded.

In *Science* for January 22, 1904, there is a short article on certain peculiar anomalies in animals and their explanation according to Mendel's law. For instance, the long-haired horses, the so-called Oregon Wonder Horses, that have been on exhibition in many of the museums of the country, would seem to be a distinct example of certain Mendelian principles, causing a characteristic to assert itself in succeeding generations after it has once become established. Linus II, a magnificent example of the long-haired horse, had a double mane which trailed on the ground on either side for a distance

of two feet. His sire, Linus I, had a mane that was single, but at 14 years old was 18 feet long, while his tail was 21 feet long. The dam also had a remarkable growth of hair. The paternal grandmother was known as "The Oregon Beauty," and was noted for the mass and length of her hair. If, however, as has been claimed, the race of long-haired horses is dying out, then this quality in the race was to use Mendelian terms recessive, rather than dominant, as Professor Castle, of Harvard, suggested in a previous number of *Science*.

According to Mendel's law, when plants or animals are bred with regard to a single characteristic, then 25% of the descendants not only present this characteristic, but transmit it unchanged to their descendants. Another 25% have not the quality present, yet it appears in a definite proportion of their progeny. The remaining 50%, though apparently presenting the dominant quality, are a mixed race with qualities from both parents, some recessives and some dominants, but once more in definite proportion. As has been well said, the application of these principles promises to be of as much service to science as the law of multiple proportion in chemistry, which it recalls in many ways.

Mr. C. B. Davenport, of the Hull Zoologic Laboratory of the University of Chicago, who writes with regard to these long-haired horses in the number of *Science* just mentioned, has also collected observations with regard to polydactylism in cats. In these cases the Mendelian principles of dominance and recessivity of qualities holds during four generations carefully observed. Mr. Davenport also quotes from Struthers a case of polydactylism in man, in which the resulting offspring during successive generations can be best explained on the Mendelian hypothesis. In this case he suggests that if we calculate the proportion of abnormal individuals in accordance with Galton's law, we should get only 33% instead of the actual 50% that were noted, and Mendel's law accords better with the facts than that of Galton. He quotes some cases of such anomalies in which apparently neither Mendel's nor Galton's law of inheritance will apply. So far, however, such exceptions have, as a rule, proved rather to be due to a lack of knowledge of all the conditions necessary in order to understand the problem of inheritance presented in the special case rather than to any actual exception to the law.

In a word, we are in the presence very probably of a complete revolution of our knowledge with regard to heredity for, as Professor Bailey, of Cornell University, said at the beginning of last year, the teaching of Mendel strikes at the root of two or three difficult and vital problems. It presents a new conception of the proximate mechanism of heredity. The hypothesis of heredity that it suggested will focus our attention along new lines, and will, we believe, arouse as much discussion as Weissmann's hypothesis, and it is probable that it will have a wider influence. Physicians may well, by careful observations in the scope of their work, bring about a further confirmation and application of these principles.

Football in 1903.—Although the physical injuries and deaths due to football are by no means the worst of its evils, they are sufficiently considerable to cool the

ardor of all but the advertising colleges and their professional "educators." The *Journal of the American Medical Association* has again done an excellent service in collecting the "accidents" in 1903. There occurred 35 deaths and over 500 severe accidents to players. Beside these 35 deaths, there were 11 cases of spinal injuries, followed by paralysis, which in most cases seem to have been permanent, and, consequently, worse than death. Sprains, contusions, and scalp wounds have not been included in the list, although reports show that many of these injuries that were at first considered trivial finally resulted seriously. There were 343 fractures, most of them of the bones of the leg and forearm. There were 91 cases of fracture of the clavicle, 19 fractures of the femur, and 4 of the skull. The *Journal* adds: "It is, of course, impossible to estimate accurately the number of permanent injuries received in these accidents, but when we consider that many of the fractures were compound, and 19 of them of the femur, we must believe that in this class alone the percentage of permanent injuries could not be very low. We can, without exaggeration, say that at least 50 deaths or permanent total disabilities resulted from the football games of 1903."

Feeble-minded Women.—In one State, Indiana, there were last year 404 feeble-minded women in the asylums for the poor; 170 of these were between 16 and 45 years of age. One of these women had borne 12, another 11, another 8 children. Five had had 19 children, and of these 19 the histories of 15 had been looked up. These 15 had been maintained at public expense a total of over 104 years. Assuming that it had cost as little as \$100 a year, they have cost the State already over \$10,000, and 10 of them are still on public support, which last year cost \$1,163.10. This is one small item in one State. What would the figures be for all the States? Everywhere these women are freely allowed to propagate their kind unchecked by law or the simplest dictates of prudence. What folly it is to keep these diseased and useless wrecks at public expense and allow them to multiply their numbers, which must also be supported by the taxpayers. The stock farm carried on after that plan would soon end. In Indiana the disgraceful condition has aroused such a reaction that provision for the care of feeble-minded women has been made, and 90 women who are unable to control themselves are at least prevented from bearing children afflicted in the same way. The women are largely self-supporting. Every State should have similar institutions.

High taxes for the billboard nuisances are proposed by Governor Murphy, of New Jersey. He has caused an enumeration to be made, and finds that no less than 1,600 signboards of all kinds, "disfigured by all sorts of effigies of impossible men and women . . ." and advertising "remedies for all the ills that human flesh is heir to, as well as all sorts of foods and drinks," greet the passengers on the railway trains as they pass through different sections of New Jersey. The scores of thousands of men and women who live in the New Jersey towns and cities near New York are compelled,

whenever they come to or go from the city, to pass a long procession of monstrosities as advertising signs. Many of these hideous advertisements are of nostrums, advocating self-treatment of diseases of which the patient knows nothing, by drugs of which he knows less. They are, or should be made, criminal offenses, but in the present condition of the public mind they may not be legally proved such, and the commendable plan of Governor Murphy should be seconded by the railway companies, by Legislatures, and the public. The nuisance may in this way be abated, at least to some extent, and a railway journey not be made a source of disgust to all rightminded people.

EDITORIAL ECHOES

"How Dissensions Grow."—His location chosen, say in a community where there are two physicians already, the young doctor is fortunate if he is not met at the threshold, the most sensitive and impressionable period of his life, with ill-concealed sneers, or complete ostracism by those already established in practice, which will grow if he succeeds, or rapidly disappear if he proves a failure. With time, and an arm's length acquaintance which can not be avoided entirely, he will probably learn that one or both of his professional neighbors practically dropped their studies at graduation; that they receive little or no new literature, except the free copy advertising journals; that they have no proper equipment for the emergency surgery they must do, or pretend to do, while time was habitually given over to petty professional bickerings and contentions sufficient to have made both of them scholars of no mean attainments in medicine, as well as in general knowledge, had it been utilized in single, or better still, in joint study. Although they constantly need each other's advice and help as no other men ever can do, he is likely to find that this spirit of envy and jealousy, pitched on a plane low almost beyond conception, not only deprives them of these, but so divides them and impresses the community as to greatly lessen the respect and confidence due both of these otherwise worthy men, as well as the great profession which they alone represent in that community. He will find that they often quarrel about diagnoses in which both were wrong; about patients who would not pay either of them, or about violations of the code which neither of them have read; that each is afraid to collect his hard-earned fees for fear the other will inherit some of his offended patrons; that ambition for excellence in surgery or other special work is dwarfed by the fact that one will send for consultation, or send his surgery, to a distant town or city rather than ask the assistance of his neighbor, and that even their families are so estranged as to be deprived of social relations and pleasures, of which both are most deserving. In a word, our graduate is likely to find that this canker of envy and jealousy which clings to our otherwise noble profession with such tenacity, and blights and curses, and curses and blights, all to which it clings, not only bars or makes all advancement difficult, but so interferes with all the social and other interests and purposes of the profession as to destroy his ideals of life.—[J. N. McCormack, *Journal American Medical Association*.]

Would Limit Sale of Cocain in New York City.—A movement has been inaugurated to prohibit the sale of cocaine by local druggists without a doctor's prescription. It has a tremendous sale in that city, and the "cocain habit" is increasing at an alarming rate. Persons have little trouble getting the drug at drug stores. Some say that it is a good remedy for toothache and other minor pains, and this explanation seems to be sufficient for certain druggists.

AMERICAN NEWS AND NOTES.

GENERAL.

Panama's Sanitary Inquiry.—A Southern Senator has introduced a resolution in Congress authorizing the Committee on Health and Quarantine to investigate health conditions on the Isthmus of Panama, and directing the committee to make a report concerning the effect of gambling and other vices within the canal zone.

Miscellaneous.—ILLUSTRATED REVIEW OF PHYSIOLOGIC THERAPEUTICS offers the sum of \$1,500 in cash prizes for the best essays on röntgen rays in medicine and surgery, the first prize being \$1,000. Surgeons, physicians, and hospitals, interested in any branch of röntgen ray work may write to the above journal at 19 East Sixteenth street, New York City, for particulars.

Would Settle the Race Question.—According to newspaper accounts an Indianapolis physician is treating an infant negro by exposure to red light in the hope of preventing the deposition of the natural pigment in the skin and thereby the indelible mark of Cain. A notice from the far West states that a similar attempt is being made for like purpose with radium. This experiment has previously been tried with röntgen rays without success. When one reads of the number of different experiments—so-called—which have been and are being performed with the röntgen rays and radium, many of which must inevitably fail, he is struck with the idea that these poor hobbies are being ridden hard unto death.

EASTERN STATES.

Sufficient Reason.—The Harvard Medical School experts who are going to the Philippines to study smallpox germs have a method in their apparent mania. They will carry on their operations in some of the distant islands of the archipelago, not because smallpox prevails there, but because monkeys are many and antivivisectionists few.—[*Boston Transcript*.]

NEW YORK.

Overcrowded Condition of Hospitals.—Great complaint occurs in newspapers from the authorities in charge of various hospitals in New York City that these institutions are very much overcrowded at the present time. Attention is called to the fact that if any serious catastrophe should occur, such as the recent theater fire in Chicago, there would be practically no hospital in which the afflicted could be placed.

"Medical Library and Historical Journal."—The announcement for 1904 of this journal has appeared, containing a partial list of the contributors. The initial number appeared in January, 1903. It now starts on its second year, its purpose being to present in an attractive literary form the important historical events, discoveries, and individual efforts having a distinct bearing upon the profession of medicine.

Guarding the Public Health.—The New York State Medical Society recently adopted a resolution advocating the passage of a bill which will give the State Commissioner of Agriculture the power to prosecute persons who counterfeit "certified milk labels," which are given by Boards of Health to milk dealers whose stables come up to a prescribed sanitary test. The movement is in the interest of sanitary milk supplies for cities.

Pneumonia in New York.—The New York Times of January 25, commenting upon the prevalence of pneumonia in that city, states that the outlook is gratifying for the entire city. The deaths from pneumonia the week previous were 329, as against 363 for the week ended January 16, and 364 for the week ended January 9. It holds the hopeful view that the prevalent epidemic of pneumonia has reached its height, and is now on the decline. Similar conditions prevailed in 1900; both influenza and measles then assumed the epidemic form, and the deaths from pneumonia reached from 250 to 400 per week through the months of January, February, and March.

"Albany Medical Annals."—The twenty-fifth or jubilee number of this journal appeared in January. It comprises a volume of more than 200 pages, and is altogether a commendable result from the labors of both the contributors and publishers. The important articles appearing in this number are: Four Cases of Gangrene, by Albert VanderVeer and Edgar A. VanderVeer; Medical Annals—Autobiographical, by Frederic C. Curtis and Willis G. Tucker; Lipoma of the Intestine, by Samuel D. Ward; Myasthenia Gravis, by Henry Hun; Acute Ascending Paralysis of the Type of Landry, by H. C. Gordinier; A Consideration of the Efficacy of Antitoxin in the Treatment of Diphtheria, by Joseph D. Craig; Nervous Dyspepsia, by Andrew MacFarlane; The Islands of Langerhans in Congenital Syphilitic Pancreatitis, by Richard Mills Pearce; A Study of the Changes Occurring in the Endometrium During the Menstrual Cycle, by H. Judson Lipes; Pathology and Treatment of Tetanus, with a Report of 3 Cases, by Arthur W. Elting; Plea for the Rational Administration of Chloroform as

a Routine Measure in Labor, by Spencer L. Dawes; Etiology and Diagnosis of Ozena and its Relation to Pulmonary Tuberculosis, by Clement F. Theisen; Starch Digestion in Infancy, by Henry Larned Keith Shaw; Etiology of Summer Diarrheas of Children, and of Dysentery of Bacterial Origin, by Herbert D. Pease and Henry L. R. Shaw; Cysts of the Mesentery by Alvah H. Traver.

PHILADELPHIA, PENNSYLVANIA, ETC.

Bequests to Charity.—Newark, N. J. By the will of Joseph Nichols, who died some 20 years ago, \$11,000 was left to the City Hospital Fund. This sum and the accruing interest, which have lately been turned over to the Mayor of the city for that purpose, amounted to \$24,000.

The Medicolegal Society of Philadelphia held its annual meeting on Tuesday, January 26. The following officers were elected for the ensuing year: President, Dr. J. C. Cooper; Vice-Presidents, Drs. John R. Umstead and Justus Sinexson; Secretary, Dr. W. T. Hamilton; Treasurer, Dr. G. M. D. Peltz; Censors, J. H. Wolfe, Drs. William Ruoff and E. W. Tulley.

New Hospital for Epileptics.—News from Scranton, under date of January 27, says: "Surveys have been completed on the Moosic Highlands at Fairview, between Carbondale and Honesdale, of land designed as a fit location for the proposed State Hospital for the cure of epileptics and for which the last Legislature made provision. It is 2,200 feet above tide."

Mortality in Philadelphia.—For the week ended January 30 the total deaths were 560 from all causes, 180 or over 30%, were caused by diseases of the throat and lungs, while but 47, or a little more than 8%, were due to the 4 contagious diseases, typhoid fever, smallpox, scarlet fever, and diphtheria. Deaths from diseases of the throat and lungs occurred as follows: Pneumonia, 66; bronchial pneumonia, 31; bronchitis, 16; congestion of the lungs, 11; and tuberculosis, 56.

New Pavilions for Tuberculous Patients.—At the Philadelphia Hospital the new glass pavilions for the housing and treatment of tuberculous patients have been completed. There are 6 of the pavilions at the hospital, each made to accommodate 18 patients. Each is a building in itself, with glass roofs and glass walls, and no more metal about it than is needed for the framework. The floor is of cement, so that all the surfaces are as smooth and as nonabsorbent as possible. Each pavilion is 27 feet wide and 36 feet long, surrounded on all sides by a 6-foot porch, so that the total area is 39 feet by 70 feet. The porches are also enclosed with glass. The inside glass is ribbed sufficiently to make it opaque. The glass of the porches is clear and transparent. All of the glass is arranged in frames reaching from the floor to 10 feet above it, and these frames, in both walls and porches, open like doors. The opening is effected by an automatic device, and any one side or all four sides at once may be opened if desired. Above the opening doors, which form the lower part of the walls of the pavilion, are other glass frames, which also open, so that the whole may be turned into an open shed with a glass roof.

SOUTHERN STATES.

Tuberculosis Exposition at Baltimore.—This exposition, which was recently held, is reported by those in attendance to have been essentially successful in its undertaking. It was educative not only in the medical sense but in the popular sense. Those having it in charge are commended by the numerous friends and visitors for the efficient, capable and instructive manner in which the exhibit was displayed. Rules for the care of personal health were hung in a conspicuous place and attracted much attention. They were: "Live in fresh air constantly; do not be afraid of cold or damp weather. Be outside all the sunny hours of the day. Avoid overheated and ill-ventilated rooms and keep the windows of your bedroom open all night. If you avoid a draught of air you need not fear a cold. Do not overclothe yourself; wear woolen garments next the skin, but do not wear more clothes than healthy people wear. A cold sponge bath every morning will make you less liable to take cold. Drink much milk and eat as much as possible, even if you do not care to." Announcement has been made that the Canadian government will probably hold an exposition of similar character next year. There were many Canadian visitors at the exposition.

WESTERN STATES.

Typhoid in Columbus, Ohio.—News under date of January 28, says: Since January 1, 560 cases of typhoid fever have been reported in Columbus, and there have been 19 deaths from the disease. The largest number reported for a single day was 48. The health authorities claim that the prevalence of the disease is due to contamination of the water in the Scioto River.

Missouri Valley Medical Society will hold its next meeting at Lincoln, Neb., March 24 and 25, 1904. Those desiring to present papers should send their titles to the secretary, Dr. Chas. Wood Fassett, St. Joseph, Mo., not later than February 20. Papers will appear upon the program in the order in which they are received. A symposium on pneumonia, followed by personal experiences, will be a feature of the program.

Embargo on Hospitals.—It appears that a conflict has arisen in Chicago between the Board of Health on the one hand and the superintendents of hospitals on the other. A city ordinance has been passed which requires that each hospital ward shall contain so many cubic feet per patient. Hospital superintendents claim that the amount of space to each individual is excessive, unnecessary, and seriously limits the hospitals in the number of patients which they can receive. The Board of Health, on the other hand, is seeking to enforce the law. It appears that litigation will be resorted to for settlement of the controversy.

Method of Compiling Vital Statistics.—The Bulletin of the Chicago Health Department, for the week ended January 9, says: At the close of the census year 1900 the department, after study of the conditions and correspondence with vital statisticians elsewhere, decided to adopt an increase of 3.5% annually as the basis of the estimated mid-year population of the city. This is 1.9% less than the rate authorized by the United States Census Office, which has accepted the English Registrar-General's method, to wit, that the same rate of increase will hold good as in the previous intercensal period, that is, that the population increases in geometric progression, or as by compound interest. As the rate of increase was 5.4% per annum during the intercensal period of 1890-1900, the mid-year population of 1904 would, if computed on this basis, be 2,096,300, instead of 1,950,000, as conservatively estimated by the department on the basis of a 3.5% annual increase.

FOREIGN NEWS AND NOTES

GENERAL.

Would Vaccinate Calves.—An exchange says: Every calf in Germany will be vaccinated with specially prepared human tuberculous bacilli upon the attainment of its third month, if the proposals of Professor Behring, the great bacteriologist and opponent of Professor Koch's tuberculosis theories, are adopted by the Reichstag. Professor Behring earnestly pleaded the adoption of an imperial law to this end, in conference with the Ministry of Agriculture. The professor also proposes to add 1 gm. of formalin to every 10-quart can of milk. He maintains that fresh milk contains elements fatal to disease bacteria, but that it quickly loses them. Formalin, he adds, would conserve these elements indefinitely. Professor Behring has interested Berlin's milkmen in his plans.

Probably another Idle Dream.—News from St. Petersburg, under date of January 27, says: "Professor Prince Tarkhanov, a well-known scientist, lecturing recently before the Military Association, made some interesting statements in regard to the possibilities of radium. He presented to his audience 2 cancer patients who had been cured of malignant growths on the face by the use of radium, and expressed the opinion that the problem of determining the sex of children, which Professor Schenck had failed to solve, will soon be settled by the aid of radium. The Prince added that he had prevented the development of hydrophobia in dogs inoculated with the virus of rabies, by using radium. When large quantities of radium were available, the Prince contended, the whole system of modern warfare would be revolutionized, as powder magazines, whether in forts or in the holds of vessels, would be at the mercy of radium rays, which could explode them at long distances."

Microbes in Libraries.—The Berlin municipal authorities have decided to make an attempt to exterminate the microbes in the public libraries, Professor Koch having called attention to the danger of spreading infectious diseases through books loaned indiscriminately. A few American librarians have expressed their views on this subject which seem at variance, theoretically at least, with our ideas of the danger of contagion from this source. They point out what they conclude is proof of the position which they assume—namely, that there is little or no danger of contracting contagious diseases from the use of free library books. This proof is that few, if any, instances can be pointed out where persons employed in large libraries have contracted disease from the handling of books. This is not altogether conclusive; since children, the class of population which is most susceptible to infectious diseases, are not, as a rule, employed in handling books in libraries. Usually such persons employed are those who have had the ordinary contagious and infectious diseases of childhood, or at least have been exposed many times to them.

OBITUARIES.

Edmund Andrews, a widely known physician in Chicago, at the Mercy Hospital in that city, January 23, following an attack of heart disease, aged 79. He was a graduate of both the academic and medical departments in the University of Michigan, the former in 1849 and the latter three years later. Dr. Andrews was one of the founders of the Chicago Academy of Sciences and an organizer of the Medical School of the Northwestern University and a pioneer surgeon in the city, having retired two years ago. In 1857 he occupied a profes-

sorship in Rush Medical College, in which institution he taught for three years. Advocating a longer course than the two years required for graduation at that time, he, with five other physicians, established Lind University, which, it is asserted, was the first institution to require a four years' course. Lind University was absorbed by the Northwestern University in 1860. In the latter institution Dr. Andrews was appointed professor of surgery. He was a prominent surgeon in the Federal army during the Civil war. Among his inventions the best known are his braces for the correction of spinal curvature, endoscope, and a device for trephining.

Phoebe Jane Babcock Watt, one of the pioneer women in the medical profession, at her home in New York City, January 30; she was graduated from the Alfred University, and later from the New York Medical College and Hospital for Women. In 1880 she was elected professor of obstetrics in the New York Medical College and Hospital for Women, which chair she held for 12 years.

Joseph Varnum Mott, at his home in Boston, January 30, aged 53; a graduate of the College of Physicians and Surgeons of Columbia University; one time surgeon to the Metropolitan Throat Hospital, and director of the Harlem Dispensary in New York. He retired from practice 10 years ago and is noted for his charity and his gratuitous services to the poor.

George H. R. Bennett, at his home in Brooklyn, from apoplexy, January 26, aged 67; a graduate of the Medical School in the New York University in 1860; a member of various medical societies, the Brooklyn Medical Club and one time surgeon of the Twenty-third regiment.

Henry Plummer, at his home in Harrodsburg, Ky., January 20, from heart disease; a graduate of the Medical College of Ohio, Cincinnati, in 1861; one time president of the Central Kentucky Medical Society and Mercer County Medical Society.

Nels N. Glim, at his home in Ashland, Wis., January 15, from general peritonitis, following an operation; a graduate of Hamline University, Minneapolis, in 1898, and a member of the American Medical Association.

Brainerd Leaman, at his home in Leaman Place, Pa., January 28, aged 62. He was a surgeon in the Federal Army during the Civil war, having graduated from Jefferson Medical College, Philadelphia, in 1864.

Francis Rudderow, was found dead in his home in Philadelphia, January 22, aged 42; he was a sufferer from Bright's disease; a graduate of the University of Pennsylvania in 1887.

John W. Harriman, at his home in Iowa City, January 25, from appendicitis; a graduate of the University of Iowa in 1891. He was professor of anatomy in his alma mater.

E. R. Manning, at his home in Stamford, Tex., January 14; a graduate of the Missouri Medical College, St. Louis, in 1897; a local surgeon of the Texas Central Railway.

Alexander Douglas Bryden, at Carbondale, Pa., January 13, from nephritis, aged 35. He was assistant army surgeon in the Spanish-American war.

Francis Woodley Harrell, at his home in New York City, January 19, from pneumonia, aged 44; a graduate of the University of Maryland in 1870.

John H. Scally, at his home in Towson, Md., after a lingering illness, aged 33; a graduate of the College of Physicians and Surgeons of Baltimore.

Rachael A. Dickey, at her home in New London, Md., January 3, aged 79; a graduate of the Woman's Medical College, of Philadelphia, in 1867.

Robert M. Weed, at his home in Mt. Vernon, N. Y., January 26, aged 50; a graduate of the New York Homeopathic College in 1880.

Frederick Fallett Comstock, at his home in Ilon, N. Y., January 12, aged 54; a graduate of Bellevue Medical College, in 1873.

Jefferson Williamson, at his home in Ottumwa, Ia., January 16, aged 76; a graduate of Cleveland Medical College, in 1852.

Moses W. Merryman, at Atlantic City, January 24. The remains were buried in Baltimore.

George Clinton Hale, at his home in Catskill, N. Y., January 30, aged 72.

SOCIETY REPORTS

THE TUBERCULOSIS EXPOSITION.

Held at Baltimore, Md., January 25-30, and February 1, 1904.

[Specially reported for *American Medicine*.]

The Tuberculosis Exposition last week was in several respects remarkable and in one respect unique. For 12 hours daily on 5 successive days throngs of people passed through the corridors of McCoy Hall manifesting intense interest in the great object lesson prepared by the tuberculosis commission. All sorts and conditions of men came and went, and the message of the Exposition was definitely impressed on every

mind. A corps of guides conducted visitors through the various departments, telling to willing hearers the story of chart, diagram, map, picture, model, and specimen.

That students of tuberculosis were attracted from all parts of the country is not surprising, for the Exposition was worth the visit, but the sustained and increasing interest of the people was most surprising, and in this respect the success of the Maryland Tuberculosis Commission was unique. Their show was a sort of continuous performance, beginning at 10 each morning and continuing until 11 o'clock each night.

The formal program began on Monday night, when the Exposition was opened by the Governor of Maryland, Mr. Warfield, who expressed his interest in the subject and his approval of the commission's method of presenting it. Honorable Robert McLane, Mayor of Baltimore, made an earnest address, dwelling particularly upon the necessity of popularizing all such movements. Dr. William Osler spoke briefly and forcibly of the apathy of great cities in general upon sanitary subjects, and particularly with respect to familiar plagues such as tuberculosis. The address of the evening was given by Mr. Frederick Hoffman, of Newark, N. J., who spoke on the **Statistical Laws of Tuberculosis**. This address was heard by a large and attentive audience, and, moreover, it was understood. Mr Hoffman's paper dealt with the experience of the Prudential Life Insurance Company with tuberculosis among the industrial classes, and emphasized the need of health laws governing shops, factories, and tenements. Any attempt to deal successfully with the problem of tuberculosis prevention must needs proceed along lines of a comprehensive statistical investigation, for the laws and tendencies of this disease are most intelligently expressed by statistical averages reduced to a uniform basis readily susceptible of critical analysis. The mortality from tuberculosis has progressively declined in American cities for more than half a century. The tendency toward a progressive decrease in the mortality from this disease from decade to decade during the past 40 to 60 years has been practically the same in all of the principal American cities. In other words, the observed decrease in the mortality from tuberculosis antedates by many years the great discovery of Professor Koch and the relatively recent view that the disease is of a highly infectious character, and is transmitted from man to man. This decrease in the mortality from tuberculosis in past years, or let us say, previous to 1890, must be ascribed primarily to a profound change for the better in the mode of life of the masses. There is great need of a broad basis of sound knowledge for any far-reaching sanitary or other measures which may be adopted for the purpose of diminishing by associated effort the largely preventable amount of disease and mortality from tuberculosis. The facts would seem to warrant the view that it is possible to so localize the mortality from tuberculosis that an energetic campaign against tuberculosis will be certain to produce far-reaching results. If we determine upon a campaign against tuberculosis as we find it to occur among persons in certain recognized unhealthy employments, or living in certain recognized unhealthy localities, or under certain illhealth-producing conditions, there is no doubt in my mind but that within a few years a marked diminution in the deathrate will result from such well-directed and intelligent efforts. By preventing the disease in the first place it will not be found necessary to erect immense and costly institutions for the cure of the disease. Hoffman is certain, from a careful study of the facts in the case, that such efforts should be primarily directed against unsanitary workshops, illhealth-producing occupations, and the employment of physically unfit types of persons in industries in which the deathrate from tuberculosis is extremely high. By adopting intelligent measures in clear recognition of the laws which determine a high or low mortality from this disease a large portion of the present mortality from this disease will be done away with.

On Tuesday afternoon at 5, Dr. Lawrence Flick, of Philadelphia, gave a popular lecture on **House infection**. Dr. Flick's paper set forth his wellknown views, drawing the clear distinction which separated the tuberculous from other communicable diseases. He laid particular stress upon the need of prolonged exposure or of heavy infection or of subjective predisposition as prerequisite to effective implantation of tuberculosis, and showed that inclosed areas, as the home, offer the most favorable conditions for spreading tuberculosis.

On Wednesday night, Dr. Mazyek P. Ravenel, of Philadelphia, and Dr. D. E. Salmon, of Washington, gave papers on the tuberculosis of animals. Their lectures were announced as of interest only to physicians and medical students. McCoy Hall was nevertheless filled to overflowing. Dr. Ravenel considered **Bovine tuberculosis as a factor in the causation of human tuberculosis**, reviewing the entire literature, and marshaling the facts in support of the theory. He holds that the greater virulence of the bovine bacillus holds good for man. In concluding, he called attention to 1 point, which by itself alone proves that bovine tuberculosis is a factor in the spread of the disease in the human race—namely, the finding of the bovine tubercle bacillus in the intestinal tract of children. On this ground alone we may rest the case, even if there were not so much corroborative evidence. The proportion of cases in which this finding has been made is large, though exact figures are not at hand. The German Commission found the bovine bacillus in 4 out of 16 cases examined; deSchweinitz has found

it twice in 4 cases, and at the laboratory of the State Live Stock Sanitary Board Ravenel has found it in 2 out of 5 cases examined. We are then justified in saying that bovine tuberculosis is transmitted to the human race, chiefly to infants, in a certain proportion of instances, and is, therefore, a menace to human health. Our present knowledge does not enable us to define exactly the extent of the danger, but that it exists cannot be denied. It is, therefore, the duty of physicians and officers of health to take every precaution against the infection of man by tuberculous cattle and their products.

Dr. Salmon's paper gave a scientific evidence of the unity of tuberculosis throughout the animal kingdom. He showed that all the morphologic characteristics, which have been regarded as differentiating the various stocks of tuberculosis, could be reproduced in any stock by culture in a suitable environment, and suggested that the virulence of human tuberculosis may be constantly renewed by implantations upon the human organism of the bacillus of other mammalia. The important problems in the great subject of tuberculosis are not so simple that they can be solved by an experimenter who ignores the work of others and starts out with a few cultures of bacilli and a few experimental animals to settle the whole question by himself and on his own lines, as some enthusiastic gentlemen have discovered during the last few years. All lines of experimentation must be considered, and where there is an apparent lack of harmony the reason for it must be discovered before dogmatic conclusions are promulgated. Above all, we should endeavor to discriminate between positive and negative results, and not make the mistake of ignoring or suppressing the experiments which demonstrate something, in order that we may accept the, perhaps, more numerous ones which have not succeeded and which are absolutely barren as a source of information. The field of comparative medicine is a broad one, and it is the part of wisdom for those engaged in human medicine to look to it for the solution of those difficult problems which have so long eluded their grasp. There has been almost to the present moment just as strong a prejudice against the theory of infection from animal sources as there was formerly against the theory of infection from human sources. Clinical evidence indicating infection from animals has been ignored, explained away, or summarily rejected, just as similar evidence as to infection from man to man was disposed of before the discovery of the tubercle bacillus. And as the evidence of infection from animals multiplied and could be no longer entirely ignored the attempt was made to neutralize it or hold it in check by the erection of scientific barriers. The frequent infection of the human subject with animal tuberculosis appears to be established by scientific investigations. It is noteworthy that most of the cases having bacilli of the bovine type have occurred in children. Each of these cases forms a new center of tuberculosis infection. And it is to be remarked that these bacilli of the bovine type are pathologically very active; they are more virulent for most animals and probably more virulent for man than are the bacilli of the human type. Therefore, it appears that these new centers of tuberculosis may be the means of keeping up the activity and virulence of the disease in man. It is a striking fact that human bacilli are generally much more saprophytic in their characters and far less virulent than those of most other mammalian sources, and it seems that the human organism has the power of attenuating these bacilli and gradually making them less and less harmful. But this influence for good must be continually counteracted by the infusion of extremely pathogenic germs from animal sources.

On Thursday evening, Dr. S. A. Knopf, of New York, gave one of his very characteristic addresses, before an enthusiastic crowd, speaking on **Pulmonary Tuberculosis and the Possibility of Its Eradication Through the Combined Efforts of a Wise Government, Well-trained Physicians and an Intelligent People.** He reviewed the history of the disease, its symptomatology and the means of transmission, reviewing the latest approved methods of prevention. He gave very careful instruction with regard to children of school age, the use of alcohol, the liability to infection of those enfeebled by disease, the necessity for ample feeding, fresh air, proper clothing, etc. He considers the sanatorium most efficient in combating the disease. Much interest was aroused by the portion of his address in which he paid his respects to so-called "tuberculosis cures," exposing some of the most widely known. The best weapon to combat these and the faith healers was by education by the press, by clergymen, by teachers. Every city should have an efficient health department, tenement house commission, street cleaning department, and a board of education, all of them combining to render the city as sanitary as possible, and thus combating centers of contagion of tuberculosis and other diseases, keeping the streets as free from dust, filth and smoke as possible, preventing the construction of unsanitary, unsafe dwellings, and the overcrowding in homes, sweatshops and factories, and making of the public schools, where our children dwell so many hours, models of perfect ventilation and places for true intellectual and physical development, thus furthering the physical and moral welfare of the entire community. Our State legislators should do their utmost to enact such laws as will secure always proper ventilation and light in public and private buildings. State Boards of Health should receive ample appropriation to combat tuberculosis among men and animals, and be helpful in creating State sanatoriums and agricultural colonies for tuberculous adults and seaside sanatoriums for

scrofulous and tuberculous children; also special hospitals and tuberculosis dispensaries, and lastly, the United States government should, after the example of Great Britain, France and Germany, not only have a ministry of public health, but also a special commission, appointed by the President of the United States, composed of expert sanitarians, physicians and veterinarians, who should unite with the State and municipal sanitary authorities of the country in the combat of tuberculosis in all its forms among man and beast.

On Friday evening Dr. George J. Adami of Montreal, made an address on **Facts, Half Truths, and the Truths, with Special Reference to Tuberculosis**, and this address though intended for a scientific audience also filled McCoy Hall. He sketched the history of doubt concerning the nature of tuberculosis and showed the necessity for scientific deliberation and caution in the interpretation of facts.

On Saturday, afternoon Drs. William H. Welch and Charles H. Potter gave lectures on tuberculosis with lantern illustrations, and in the evening Dr. John B. Huber of New York, gave a similar, though more popular, illustrated lecture.

On Monday February 1, Dr. William Osler gave a lecture on **The History of Tuberculosis** using the remarkable collection of books collected by himself and Dr. Henry Barton Jacobs to illustrate the development of the subject from the earliest times. The beautiful exhibit was shown under glass, the books, beginning with a sixteenth century edition of Hippocrates, being opened so as to show the most striking passage on the subject. About a hundred linear feet of cases were required to hold these books.

A very complete pathologic exhibit was arranged in a room somewhat apart from the remainder of the Exposition and competent demonstrators were on duty all the time.

The popular features of the Exposition began with the display of charts and diagrams showing the prevalence of tuberculosis, its varieties, its relations to race, age, sex, habits, social and economic conditions. The charts on the economic relations of tuberculosis in Maryland were of particular interest, and quite novel. They were prepared by Dr. Marshall L. Price, the Medical Officer of the Tuberculosis Commission, and traced many tuberculous patients through their periods of partial disability and of total disability to death. Maximum and minimum charts were shown for the tuberculous wage earners of greatest and least earning power. There were also comparative charts showing the economic differences between the course of tuberculosis and other chronic diseases.

After the statistical department came the department of tenements, sweatshops and factories, very liberally illustrated.

Next came the department of State and municipal hygiene, and next the department of sanatoriums which included all the variations of the sanatorium idea with abundant details as to cost of construction, maintenance, and equipment, and statistics of results obtained here and abroad.

Next followed the department of Home Treatment and House Hygiene where one might learn the minutest details of safe management of the tuberculous patient in the home. This department included an exhibit of the work done by instructive visiting Nurses' Associations.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

REMARKS BEFORE THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

BY

A. JACOBI, M.D.,

Chairman of the Joint Committee on Conference, January 26, 1901.

The report of the chairman of your Committee of Five encloses the work of the Joint Committee of Ten. As its chairman, I rise to add a few remarks to the complete historic review you have listened to. I do so with the expression of the most intense gratification. For it has never been my lot to assist at the labors of any body of men more engrossed by their work than this committee laboring for the consolidation of the 2 large State bodies.

The report before you gives no idea of the time and efforts required by the task entrusted to this committee. At first it seemed we had plain sailing. Nothing appeared to be simpler than to consolidate 2 corporations eager to be consolidated. A large amount of detail work was expected, but the enthusiasm exhibited in the Association and in the special October meeting of the Medical Society promised an easy fulfilment of our com-

¹ Made after the reading by Dr. Henry Elsner, chairman of the Committee of Five of the Medical Society of the State of New York, of the proposed Agreement, Constitution and By-laws.

mon intentions and wishes. There was perfect harmony. There never was an allusion to past difficulties, controversies, or animosities; nor was during the many and protracted meetings a single minute disturbed by the rumors spread now and then of alleged attempts at thwarting the will of the profession as represented in the Joint Committee. Its two halves worked with equal zeal; naturally, the actual work could not be equally divided; without invidious discrimination, therefore, the chairman wishes to thank 2 members for the unusual amount of labor cheerfully undertaken and successfully carried out—namely, the chairman of your Committee of Five, Dr. Elsner, and the secretary of the Joint Committee, Dr. Wisner R. Townsend. Nor should I pass by the uninterrupted and unselfish aid unofficially given by our president, Dr. Algernon T. Bristol, and our legal counsel, Mr. Howard van Sinderen, without whose indefatigable cooperation and fertile resourcefulness we should have stranded many times. In connection with this statement, I wish it to be understood that whatever has been done by your committee, whatever has gone before the Legislature, or has been presented to you, has been scrutinized, suggested, criticised, or created by him.

The Legislature has not been slow in appreciating and rewarding the efforts of the medical profession in behalf of its unification. Those of us who lived in by-gone times and participated in the work of this society, are aware, that it took years of strenuous effort and persistent persuasion to convince legislators of the importance and general usefulness of State Boards of Examiners, of increased requirements for the matriculation in medical schools, etc. When at those different times we approached the Legislatures we were always confronted with the reproach that the medical profession was no unity, that what one wanted the other opposed, and with the fact that legislators declared themselves unable to decide a question in regard to which medical men were not of one mind. We were told many times, that if and when the medical profession came before the Legislature as a united body with demands, either in its own or the people's interest—both, as a rule, being identical—there would be no delay in complying with its wishes. That promise has been made good. Within a week the permissive bill asking for consolidation has been passed through the Senate, and the Assembly, and signed by the Governor. Our thanks are due to the kindly services of the Hon. Nathaniel Elsberg, and his and our friends in the Senate and Assembly, and the Governor, the Hon. B. B. Odell. Evidently there is no power in the land that would care to evade, or to disapprove, or claim a just ground to withstand the reasonable demands of the 11,000 physicians of the Empire State when united for a common purpose.

The Legislatures of the future will be glad to know that whenever a bill will arrive that is voiced by the united profession and deals with the sanitary, educational, and other vital interests of the people of the State, they are safe in passing it. The mature judgment of the profession has not easily been mistaken. Indeed, whatever progress has been made in the scientific and moral evolution of the medical profession has been accomplished by the combined efforts of its rank and file, without the cooperation, and frequently against the opposition, of some medical schools or of alleged and self-complacent leaders. That is as it should be in a profession which is imbued with the democratic principles of the Commonwealth, and with the consciousness of its predominant weight in the determination of the most vital interests of mankind.

From the report read, you learn that the consolidated medical profession will bear the time-honored name of the Medical Society of the State of New York, that its seal will be preserved, its continuance not interrupted, and the individual rights of members enhanced. There will be no privileged class of almost 500 permanent members, some of whom have even lost their membership in county societies, and no danger from a possible predominance of such an aristocratic class. The house of delegates will count at least 150 members, in place of the Nominating Committee of Nine. It cannot elect its own members into offices. It is controlled by the referendum, which means an appeal to the total membership of the society in any doubtful or contested case. It takes the place of Congress in our political commonwealth. To it are referred legislation and administration, and it is renewed by annual election

in the county societies according to the number of assembly districts, with this proviso—that every county society has at least one delegate. By being the legislative body, it leaves the meetings of the society free for its scientific work. The constitution and by-laws, formed under the eyes of legal authority, are safe from interference and are subject to changes by the majority vote of the medical society.

This is what is proposed for your adoption. Other points are referred to the future vote of the combined societies, so the question whether there shall be in the by-laws an ethical clause, whether the directory or journal or transactions shall be continued or not and the amount of dues. All this will be left for your 5,000 or 6,000 votes to decide.

You who met here as delegates or permanent members are in as momentous a position as any that the medical society was ever placed in during the century of its existence. Unification has been the demand of the vast majority of the profession of our State so long, that it has become practically unanimous. Not of the State alone, however. The profession of the United States is listening to your verdict of this morning. While it is our pride that this is so, and that on our resolution the fate of the country's profession may depend—to know that the eyes of our brethren all over this broad land are upon us this very moment, adds to our responsibility. Never was there during the life of this society a better opportunity for the display both of wisdom and of patience.

It is admitted on all sides that both patience and wisdom are demanded more on the part of the medical society than of that of the Association. The latter's organization is simpler, and being younger it is not beset with old, in part contradictory, often repealed, frequently only half-repealed laws extending over a hundred years. The autonomy of the county societies, which the Joint Committee has been anxious to preserve, unless wisely exercised creates a difficulty. As their ratification of the new constitution and by-laws is demanded as a matter of course, their common sense, patience, wisdom and patriotism are required to a high degree. They will consider that laws are not made for ever; laws are not the masters of men, but the expression of their will as modified by time, usages, and changed necessities. Even the sacred Constitution of the United States had to be modified by the modern requirements of the sons and grandsons of its makers. That is why it is recommended that if there be any points in the proposed constitution and by-laws displeasing one or the other, you are still safe in adopting them all. There are six thousand of us, and there will be more. Every year your constitution and by-laws may be altered if you deem proper. Your delegates will change, and your referendum is more powerful than any house of delegates. What we are after, is union. More than once a member of your Joint Committee got up to say: "We have been sent here to harmonize and to unify and to consolidate. We cannot return to our masters and tell them we have missed our opportunities to execute their will. I still hear the ring of enthusiastic applause when the unanimous vote calling for unity brought a tear to many an eye. And unity it shall be." I never heard the duties of sound citizenship expressed more emphatically.

After unification, we shall be satisfied that nothing will ever sever us again. For there will never again be a diversity of principles like 22 years ago. There will be a common faith, aim, and altar. We shall take, in the medical brotherhood, the place which belongs to us, and work for the ideals, scientific, moral and practical, such as no other profession can realize, together with our peers all over the union. We must or need split up into parties nevermore. To the undivided and indivisible body medical the American people will look for authoritative guidance in matters of sanitation, education and forensic legislation. What a Greek sage demanded should and may become true, viz., that the Commonwealth will be advised and ruled by the physician. It is in this spirit that I appeal to you not to miss this opportunity of initiating for our glorious profession an epoch of fraternity, vastly increased usefulness, and almost ideal possibility for benefiting ourselves, our brethren, and numerous millions. I appeal to you as one of your oldest members who has stood by you in prosperity and distress, in peace and in war; and long and lately as a friend of reconcilia-

tion and union of the 2 great medical bodies of the State. The confidence both of your own committee and that of the Association has permitted me to preside over their long and laborious deliberations. That is why I feel I have a right to represent in this solemn hour the whole profession of the State in its anxious longing for consolidation, not as an officer, or a delegate, but as a peer among peers. That is, Mr. President, why I have risen to move the adoption of the following resolution:

Resolved, That the report of the Joint Committee of Conference be accepted and that the proposed agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association be and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name and behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereunto; and be it further

Resolved, That the committee of the society heretofore appointed for the purpose of bringing about the consolidation, namely, Dr. Henry L. Elsner, Dr. A. Jacobl, Dr. A. VanderVeer, Dr. George R. Fowler and Dr. Frank Van Fleet, be and they are hereby continued as such committee, with full power and authority to do whatever may be necessary to carry the agreement into effect.

A CASE OF HYDROPHOBIA WITH AUTOPSY.*

BY

G. MORTON ILLMAN, M.D.,

of Philadelphia.

I think it prudent to report this case for discussion, because of the fact that proper precaution, protecting human life from one of the most distressingly fatal infections known to mankind, is overlooked, especially in the large communities of America. In some instances the very existence of the condition is questioned by a few members of the medical profession and by the laity.

The patient was a well-developed male, aged 37, and an electrician by occupation.

Family History.—His family history was negative, with the exception of the fact that his mother died of pulmonary tuberculosis.

Previous Medical History.—Investigation as to the previous medical history showed that the patient had been a comparatively healthy man with the exception of a slight persistent cough, with which he had suffered some years ago, but which had ceased after the patient discontinued the excessive use of tobacco.

Two years ago the patient met with a severe accident, necessitating the partial amputation of three fingers of the right hand. This accident was followed during the present year by a severe burn of the right arm and forearm. The patient was just recovering from the latter condition when, upon attempting to caress a strange dog, he was bitten in the palm of the left hand, in the web between the first two fingers.

The wound was thus inflicted August 23, 1903. It bled freely at the time and was cauterized one hour later with a solution of silver nitrate (of questionable strength), followed by pure carbolic acid, and an antiseptic dressing applied. The wound healed kindly without any decided complications.

Premortuary Stage.—In the evening of October 1, 1903, just 39 days after infliction of the wound, the patient's attention was attracted to his left hand by a tingling sensation in the tips of the fingers and in the cicatrix. His wife states that during the following two days he appeared greatly depressed, restless at night, had little or no appetite, and complained of a constantly increasing aching sensation in the left hand and arm.

Spasmodic Stage.—Upon arising from bed in the morning of October 4 the patient complained most decidedly of the left hand, arm, and shoulder, and of a pronounced feeling of debility. He went to breakfast, however, as usual, and while at the table asked for a glass of water, and upon attempting to swallow the liquid it was suddenly and involuntarily expelled from his mouth. He then went upstairs without assistance and lay upon a couch, complaining at the time of feeling extremely weak.

At 10 o'clock a.m. I was asked to attend the patient, and found him decidedly restless, and complaining, in addition to the aching arm and shoulder, of being very chilly. The skin was moist, the muscles relaxed, reflexes normal, and face flushed. Pressure along the nerve trunks and muscles of the left arm and shoulder was slightly painful, but did not seem to be productive of any local or general spasm. Attempts at prolonged conversation, however, seemed to cause, from time to time, a sudden involuntary laryngeal spasm, after which the patient would be unable to resume talking immediately because of a marked dyspnea thus produced. The temperature at this time was 101° F.; the pulse 102; and the respirations, when regular, were 24.

Upon receiving the history of the patient's inability to

swallow water while at breakfast, I decided to prescribe an antirheumatic in powder form to be taken with water during my absence, in order to avoid arousing the patient's suspicions regarding my belief in his ability to swallow liquids as usual.

At 3 o'clock in the afternoon I was informed that after a great effort he had swallowed one powder, but that a repetition had been absolutely impossible, and, furthermore, that he had refused all liquids and solids at lunch time. There was now a pain on the left side of the neck which seemed to be most marked along the posterior borders of the trapezius and sternomastoid muscles, radiating toward the occipital portion of the skull.

The patient complained of an almost constant smothering sensation in the larynx, and the slightest efforts to talk would now very readily provoke a laryngeal contraction, during which time the patient continually held his hand to his throat in an effort to relieve his dyspnea and was extremely restless. The temperature continued to be 101° F., the pulse was 98, and respirations 26.

Feeling that future treatment of the patient depended upon an absolute surety as to the diagnosis, I asked Dr. Samuel Wolfe to see the patient, and after a very careful examination and consideration of the definite history Dr. Wolfe came to the conclusion that the case was almost certainly one of true hydrophobia. The actual state of affairs was at once explained to the family, and thus all obstacles to future treatment eliminated.

At 6 o'clock the same evening (10 hours after the first appearance of active symptoms) it became necessary to resort to hypnotics to control the spasms, which were now becoming very much longer in duration and more decided in severity. Eight mg. ($\frac{1}{8}$ gr.) of morphin and .4 mg. ($\frac{1}{250}$ gr.) of atropin were accordingly given hypodermically with a very beneficial result, enabling the patient to obtain a much needed rest of 4 or 5 hours' duration.

It became necessary to repeat this injection 6 hours later, at which time there was a noticeable hyperesthesia of the left side, especially marked at the time of puncture with the hypodermic needle. The patient's general appearance was now that of a decidedly sick man and one whose suffering was anything but of an hysterical nature, his manifest desire to assist with his treatment and avoid worrying his family being most pronounced.

The second administration of morphin and atropin had only been beneficial so far as respiration was concerned, the injection being repeated at 5.30 a.m. (5½ hours after the second administration) with better results, especially upon the severity of the laryngeal spasms, but with no decided effect upon the frequency of recurrence.

All attempts to have the patient take food of any variety by the mouth failed, and nutrient enemata (of beef) were resorted to and retained, being given always after a hypodermic injection of the narcotic.

In the afternoon of the second day of the spasmodic stage, Drs. M. P. Ravenel and D. J. McCarthy were called in consultation and made a careful examination of the patient, especially as regarded the nervous symptoms, and stated that in their opinion the case was undoubtedly one of hydrophobia.

There seemed to be a slight tendency to increased salivation during the past 6 hours, and now, regardless of the atropin that had been given, there was a moderately abnormal flow of saliva, probably caused, to a certain extent, by the almost continual movement of the patient's jaws and tongue.

With the approach of evening the general condition became gradually worse, and at 8.30 p.m. a series of spasms developed, extending over a period of 30 minutes. During this series of paroxysms there was increased salivation, intense dyspnea, rolling of the eyes, continual change of position, marked eructations of gas, and the passage at this time of about 6 ounces of urine, making 10 ounces passed within 5 hours. Delirious symptoms now became noticeable, but occurred only at intervals of 2 to 3 hours, and were of very short duration.

During the course of the next 10 hours but 2 administrations of morphin were necessary, the patient resting fairly quietly until Tuesday morning (October 6, the third day of the spasmodic stage), at which time control of the patient became a difficult matter. The excitement became maniacal, and it was feared the patient would do himself personal injury, although his entire appearance was at times one of terrible fear, and he would hold his throat with both hands in a frantic effort to relieve his dyspnea. Attempted inhalations of chloroform at this and other times gave no relief, and only seemed to increase the suffering.

After some effort .6 mg. ($\frac{1}{100}$ gr.) of hyoscin hydrobromate was given hypodermically with a very gratifying effect. This dose of hyoscin was repeated 3 hours later, and was the last administration of a hypnotic of any kind that was necessary during the remaining course of the disease. The temperature was now 101.6° F., the pulse 124, and respirations 44.

Paralytic Stage.—A few hours later a gentleman who saw the patient pronounced the case one of hysteria of a remarkable type, and was so positive as to his diagnosis that it was decided to put the patient upon hysterical treatment. Accordingly, all medicinal administrations, rectal feedings, etc., were discontinued, and no one except the nurse or a substitute allowed in or near the room. Twenty minims of sterile water was given hypodermically every 2 or 3 hours, and the nurse informed me that there was absolutely no effect as to the frequency of the spasms, but there seemed to be a steady decrease in the severity

* Read before the Philadelphia County Medical Society, December 9, 1903.

regardless of the time at which the injections of water were given. In other words, it was very apparent that regardless of treatment the patient was slowly passing into the paralytic stage of hydrophobia.

The patient now began to perspire profusely, and vomited for the first time about 4 ounces of yellowish, frothy mucus. The profuse sweating continued, and a few hours later both pulse and respiration began to fail rapidly. It became very evident that a return to medicinal treatment was necessary, and 1 mg. ($\frac{1}{32}$ gr.) of digitalin and .4 mg. ($\frac{1}{15}$ gr.) of atropin were given hypodermically with much benefit.

The periods of delirium were now of frequent occurrence and of long duration. When rational the patient declared that the choking sensation had entirely gone from his throat, and that he was now smothering from oppression over the epigastrium, and during a spasmodic attack would put both hands to this region instead of to the larynx as formerly. It was, therefore, decided to endeavor once again to administer a liquid by way of the mouth. Two ounces of milk containing a fluidram of whisky was brought to the patient, and with a little assistance and encouragement the entire contents of the glass were swallowed without any great effort. On finding himself able to swallow liquids again the patient asked for a cup of coffee, of which he drank a few drams. About 30 minutes later both coffee and milk were vomited and all efforts to repeat the same were forcibly resisted.

In spite of stimulants the pulse and respiration failed steadily and the patient became permanently unconscious, at which time 20 m. of ether was given hypodermically and resulted in a sudden general clonic muscular spasm.

External heat had been constantly applied to the trunk and extremities, and digitalin and atropin given, either together or separately as occasion demanded, until the patient's death of respiratory failure at 7 a.m., October 7, 3 days (71 hours) after the onset of active symptoms, and nearly 6 days after the onset of prodromal symptoms.

The hyperesthesia was a prominent symptom throughout the course of the disease, and became gradually more pronounced until finally both before and after unconsciousness warm applications could only be placed to the extremities very gradually and retained in position with difficulty. Hyperesthesia, as a rule, was most marked on the left side. Very slight stimulations, such as the sudden entrance of light to the room, the running of water and the ringing of the doorbell, were many times provocative of a spasm. The reflexes were increased and the plantar reaction always downward. The pupils became dilated and nonreactive about 8 hours before death.

Delirium began to manifest itself about 36 hours after the onset of active symptoms, became more prominent during the administrations of hyoscin, but was still present during the period of 9 hours when the patient was receiving no medicinal treatment, and continued to the period of unconsciousness.

During the entire course of his illness there was never made in the presence of the patient any mention of or reference to dogs or hydrophobia, and he was made to believe, so far as possible, that he was suffering from rheumatism of the throat muscles. At no time during his illness did the patient simulate in any manner the actions of a dog or other lower animal, although he frequently referred to the dog-bite as being the cause of his present condition.

The temperature showed a gradual rise until the second day of the spasmodic stage when it reached 102° F.; after which it ranged between 101.8° F. and 100° F. The respirations, when at all regular, varied from 28 to 40, and simulated at times Cheyne-Stokes' respiration, especially after a series of laryngeal spasms. After unconsciousness, ether dropped on the larynx and upper portion of the chest brought about a prompt respiratory reaction.

I had an opportunity to make but one examination of the urine, the specimen being collected during the second 24 hours, after the onset of active symptoms. It was high-colored, decidedly acid, and showed a specific gravity of 1.040; there was no albumin nor sugar present. No microscopic examination was made.

Prophylaxis.—All linens, towels, etc., used around the patient, especially those contaminated with saliva or vomit, were at once thrown into scalding water and later boiled. After death, all needles, thermometers, spoons, etc., were either destroyed or sterilized, and the floors, bedding and furniture thoroughly wiped off with a strong solution of carbolic acid.

Autopsy.—The autopsy was made 10 hours after death by Drs. McCarthy and Ravenel, with the following results:

The lividity of the dorsal surface of the body was very marked, and rigor mortis of the upper and lower extremities very well developed.

The skull was thin. The brain and membranes were normal, both over the convexity and base.

The spinal cord and its membranes were of normal appearance, as were the pancreas, adrenal glands, and spleen.

The lungs showed some adhesions in the right pleural sac, a rather marked emphysema along the anterior border of the right lung, and an area of healed tuberculosis at the right apex.

The liver showed a slight passive congestion, otherwise normal.

The heart was normal with the exception of a patch of old pericarditis on the anterior surface.

The kidneys appeared to be normal. The inner surface of the larynx was covered with dirty mucus and there was considerable frothy mucus in the trachea.

Microscopic Examination.—The microscopic examination of the central nervous system shows typical tubercles of Babes in the medulla. The round-cell infiltration around the blood-vessels was very distinct.

Sections of the cerebral cortex and base of the brain show no evidence of inflammatory change.

Sections of the gasserian ganglion and also of the intervertebral ganglions show a round-cell infiltration in the stroma, a diffuse chromatolysis of the ganglion cells, and a vacuolization of some of these cells, with a proliferation of the capsular cells, in most areas of only moderate degree, but in some areas filling up the entire capsule.

The peripheral nerves and the anterior and posterior roots show no change after careful investigation.

Microscopic study gave perfectly normal appearances in all the viscera with the exception of the kidney. These sections show some congestive swelling of the glomeruli and a cloudy swelling going on to marked degeneration of the cells of the tubules.

In other words, pathologic lesions typical of hydrophobia were found in a case associated with parenchymatous nephritis. Neither the pericellular nor perinuclear round-cell accumulation of the central nervous system nor the lesions of the intervertebral ganglions are seen in cases of nephritis.

Inoculations.—Three rabbits were subsequently inoculated from the medulla of the patient, with the result that all 3 rabbits died after a period of 17 to 19 days, presenting typical symptoms of rabies, and subsequent sections made from the nervous systems of these rabbits showed pathologic changes typical of rabies and corresponding to those found in the nervous system of the patient.

The Dog.—The dog was of the small terrier type, showed no signs of rabies, and is said to have been playing with some children only a short time before biting the patient. The killing and cremation of the dog prevented a subsequent autopsy.

I close this report with the earnest plea that an effort will be made to have constituted or enforced the proper laws, compelling the muzzling and quarantining of dogs at all seasons of the year, that society may thus be protected from this fatal condition, and that, if possible, it be thus completely eliminated, as in many foreign countries, notably Australia.

THE MISFORTUNE OF A COLLEAGUE.

To the Editor of American Medicine:—An unusually trying calamity has befallen one of our brother physicians in the fire which destroyed the property of Dr. Edwin Remick, of Farnworth, N. H., on the night of January 21.

Doctor Remick is the only physician in his town, and covers a territory so large that he often drives 15 to 20 miles in seeing one or two patients. Such service involves constant exposure and heroism in the severe winters of the White Mountains, and is but poorly compensated, when looking at it from a financial standpoint.

Early Thursday morning the doctor's family awoke to find the house in flames; the doctor had come in late and was so overcome with sleep that he could scarcely be roused. The family barely escaped barefooted upon the snow and in less than an hour the house and barn were level with the ground. All the doctor's books, instruments, and medicines, which he has to supply, there being no drug store in the place, were lost. In fact, practically everything was burned, and the property was not covered by any insurance.

It has occurred to me that readers of *American Medicine* would be interested to help our brother in his trying loss. Complimentary copies from some of our medical authors would be very acceptable, in replacing the doctor's library for instance, and other ways of showing sympathy will doubtless suggest themselves.

A BROTHER PHYSICIAN.

PURINEMIA: A CLINICAL STUDY.¹

BY

REYNOLD WEBB WILCOX, M.D., LL.D.,

of New York City.

Professor of Medicine at the New York Post-Graduate Medical School and Hospital; Physician to St. Mark's Hospital.

When a matter for medical study and observation becomes one of popular interest and assertion, then many erroneous opinions must needs be prevalent. When, as is true in this instance, the origin, action, and excretion of a substance offers considerable difficulty to physicians in reconciling theory and fact, the assumed accuracy of the conclusions prevalent among the laity are indubitably open to rigid scrutiny. It is with this fact in evidence that this paper is presented. With difficulties which experts have not solved to the satisfaction of the profession, the people are still further from a just comprehension of the questions at issue.

When even a definition, which shall be entirely acceptable, is scarcely to be advanced, may we expect harmony from discussing the subject not yet thoroughly defined? We all know pretty thoroughly, and those of us who have experienced it absolutely, what gout—open, frank, and active gout—is, both as to its symptomatology and treatment. Yet we are not unanimous whether the sodium biurate which constitutes the tophus is the cause or the result of the pathologic process. When we go a step further and discuss symptoms and conditions more or less closely allied to gout, we find so much that we can set down as common to, and nearly as much that is discordant with it, that opinions vary within extremely wide limits. To term all sorts of conditions, presenting more or less resemblance to gout, as phases of gout, gives us a point of anchorage, but permits of deviation to every point of the compass. This fact undoubtedly explains the variability of opinions, a variability not alone geographic nor chronologic, but even variable as to the individual. If we go over the various statements made as to the disease, this is fairly representative: "In gout we have a disease which may give rise to almost any symptom or affect almost any organ or function." If we start with the patient the following has been presented: "The gouty individual is one whose general metabolism is instable, and this instability may be present in one or more of the great physiologic systems (digestive, circulatory, nervous, etc.)." If these statements represented the actual state of our knowledge, the reasoning hearer might readily assume that we had abandoned our anchorage and were idly drifting on the trackless seas of speculation. In a recent contribution to the literature of this "*Dominus morborum et morbus dominorum*," Woods-Hutchinson in a most philosophic essay based largely upon the findings of comparative anatomy, offers "a disturbance of health associated with the presence of excessive amounts of urates in the urine," as a solution of the difficulties which beset us. The merit of the definition lies in its presenting a material point from which we may start in our discussions. It fails to state what the *corpus delicti* is, although deductively it is not uric acid. It fails because it does not embrace within its limits those instances of undoubted goutiness in which "the presence of excessive amounts of urates in the urine" is inconstant, and it proves too much, as the metaphysicians say, because leukocythemia and the renal infarcts of the newly-born are included by the definition, but are admittedly not involved in the question so far as the symptomatology is concerned. However, as a starting point this statement is useful, and an effort will be made to find a working hypothesis upon which we may base

a plan for relief of symptoms and disabilities consequent upon disturbed metabolism.

From the time of Scheele's discovery of uric acid, 128 years ago, until the present, that substance has been at once the base and the capstone of all pathologic theory in regard to gout. At present we are in better position to reach a practical working basis for therapeutics. 1. We are reasonably certain that uric acid, as such, is not toxic. This fact demonstrated by Graucher, in 1884, is now almost universally conceded. 2. The presence of a uric acid sediment in the urine does not of necessity indicate a gouty tendency, for the power to hold uric acid in solution in the urine depends largely upon the amount of pigment and the percentage of salts contained in that excretion. 3. A nitrogen free diet does not cause an abolition of uric acid excretion. And finally, the excretion of uric and phosphoric acid goes on hand in hand—at least during attacks.

Let us examine these propositions *seriatim*. While uric acid *per se* is not toxic, it is quite possible that earlier and less oxidized bodies are probably so. Therefore the increased excretion of uric acid signifying the increased or complete oxidation of uric acid antecedents and their elimination as uric acid, should be accompanied by a relief of symptoms referable to the presence of these antecedent bodies in the organism. In practice this is found to be true.

Next, the observation of coincidence of marked symptoms and diminished uric acid excretion with periods of relief and increased uric acid excretion, point out that delayed or imperfect excretion of uric acid is concomitant with exaggerated pathologic conditions. Since, as has just been stated, uric acid is not itself toxic, its forbears must be responsible for the symptoms. Therefore, only the quantitative analysis, not microscopic or macroscopic appearance of the sediment, will determine its amount. The analysis must determine the facts as to the amount of uric acid present in the urine, and the physician bases his work upon that finding.

As a nitrogen free diet is not followed by an absence of uric acid from the urine, the formation of uric acid in the body from substances contained in it must be conceded. This uric acid is very properly termed endogenous uric acid and is independent of the character of the food ingested. It is the exogenous uric acid, the amount varying with the food and modified by various factors which act on digestion and absorption, when the patient is on ordinary diet that completes the other portion of the total uric acid excretion.

As uric acid and phosphoric acid excretion bear a fairly constant relation to each other, the clue is at once given as to the probable source of endogenous uric acid. This source is the cell nuclei, and the products of their destruction are both uric and phosphoric acid as they appear in the urine. Therefore the breaking up of these nuclei gives rise to the appearance of uric acid and the xanthin bases which, as a group, constituting the alloxur bodies are termed purins, because they all contain the radical C_5H_4 .

The method of cleavage may be stated as follows: The nucleins break up into albumin and nucleic acid, the latter into phosphoric acid and a parent substance, which in turn breaks up into alloxur or xanthin bases and uric acid. As the metamorphosis of nuclein to adenin to xanthin to hypoxanthin to uric acid is by simple steps of oxidation, their formulas differing only by a molecule of oxygen, uric acid should no longer be considered as a product of imperfect combustion of proteids into urea, but rather that it closely depends on the amount of nucleins, purins, and alloxur group in the blood. And this is confirmatory of the suggestion that the source may be the leukocytes, since in some cases, at least, a leukocytosis (polynuclear basophilic) may coincide with the uric acid excretion, especially during or just before a recrudescence of the symptoms. Since, as we have said before, the phosphoric goes hand in hand

¹ Read before the Harvard Medical Society, November 28, 1903.

with the uric acid excretion, it would be as logical to direct therapeutic attention to the former as to the latter. So far as the endogenous uric acid is concerned, and this is the kind at present under discussion, we may define gout as a toxemia of varying causation, accompanied by the formation of an excess of urates, this excess being due to the breaking down of the leukocytes and fixed cells in the attempt to neutralize the poison. This gives us a sound basis upon which we may base our therapeutic measures.

Now as to the exogenous uric acid; obviously this comes from without, and constitutes the source of the smaller moiety of the total output of uric acid. Indeed, the ingestion of food, either purin free or of small purin content, must be considered. The chief purin free foods are: Milk, eggs, butter, cheese, white bread, rice, sago, fruits. Those containing under .02% of purin nitrogen are beer, stout, onions, asparagus, brown bread. Under .03%, oatmeal, lentils, beans, peas. Under .05%, salmon, cod, pike, halibut, mutton, veal, pork, ham, turkey, chicken. Under .1%, liver, steak, soups. Under .4%, sweetbreads. Obviously, were the attempt made to regulate the diet according to the amount of purin nitrogen found in food, various articles of food would be permitted which experience has shown to be detrimental to the patient. And after all, the patient must not be disregarded, for the metabolic reactions of the gouty are indubitably abnormal. From this it must be clear that an attempt to regulate the output of exogenous uric acid by altering the intake of purin containing substances, must be futile when we consider that there are factors influencing metabolism in the gouty which are important. This offers the second point for therapeutic consideration.

Finally, the wellknown clinical observation that the appearance of an excess of uric acid and urates in the urine is generally coincident with the diminution or disappearance of the symptoms, leads to the conclusion that the elimination of bodies antecedent to uric acid by agents which increase the uric acid output as uric acid, is another important therapeutic measure, and this constitutes the third point to be considered.

In considering endogenous uric acid, unquestionably methods whereby the toxemia which results in nuclear destruction is obviated, should be considered. Further metabolism, in character at least, is profoundly altered by the ingestion of various substances which have not, up to this point, been given consideration. Lead is notorious in its influence; lime waters and those containing iron are well known to be harmful. But not alone direct poisons are potent, but indirect ones as well. The effect of alcohol on gouty subjects is not entirely the effect of alcohol *per se*, but is more probably due to some of the more readily fermentable carbohydrates, as the ethers, esters or acetone groups which are found in the sweeter or more fruity wines used by the rich, or accessory products found in the malted beverages drunk by persons of moderate means. This has been experimentally shown. The logical deduction should be that substances capable of producing intestinal putrefaction and consequent autointoxication, should be prohibited.

If, then, the endogenous uric acid is restrained as to its amount by methods which prevent unnecessary waste from autointoxication, the exogenous uric acid can be readily controlled. Evidently a prohibition of red meat, for instance, as has been the custom, should diminish the excretion of uric acid of the exogenous variety, but we are brought face to face with the fact that the ingestion of nitrogen is essential to the organism for its existence, and so far we cannot make use of that contained in the atmosphere. The distinction between animal and vegetable foods is more apparent than real, for the glutens (vegetable albumins) at least, are assimilated with more difficulty than animal albumins, and the excess of carbohydrates leads to intestinal fermentation and putrefaction. Clinically, the red meat prohibition has not

been a success, and modern researches now tell us why this is so. To make a positive statement, it can be safely said that animal food in moderation is advisable. Pickled, salted, and fried meats are tabooed. Fish is excellent, even lobster and oysters are permissible if in good condition. All vegetables and raw fruit if apart from meals are allowable. Tea, cocoa, and coffee in moderation are permitted. Alcohol in excess and inferior wines are harmful. Malt beverages should be supplanted by cider, the quantity not to exceed a pint each day. As has been pointed out, the quantity of food is to be limited rather than the variety. All rich, highly seasoned, greasy and twice-cooked foods, strong soups, cooked tomatoes, rhubarb, sweet cooked foods, are to be avoided. Large mixed meals of animal and farinaceous foods with fruit and wine, especially if the latter be sweet or fruity, provoke the disease. Plainly cooked animal food, preferably by roasting or grilling, and limited to the quantity necessary for nutrition, is eminently satisfactory. Two ounces of good whisky per day, well diluted, will satisfy those habituated to alcohol. Excess of water should be taken only apart from meals. Sedentary habits interfere with digestion and assimilation, and lead to the ingestion of more food than the muscles and liver can burn up. In fact, excessive quantity of food, improper forms and amounts of alcohol, lack of exercise are factors which lead to gout which is earned rather than inherited. The last therapeutic fact which calls for comment is the method by which an excess of uric acid, and especially its forbears, is removed from the tissues. The alkalies and salicylates are our chief reliance in that they not only make these products more soluble, but also because they favor their elimination. The prolonged use of the alkalies is obviously disadvantageous, so that we must place our chief reliance in the salicylates.

In practical work I have endeavored to carry out the principles which have been enumerated, both in respect to diet and physical measures, and further to make use of an agent which would (1) limit intestinal fermentation; (2) render uric acid and its forbears more soluble, and (3) facilitate their elimination. The method comprehends both the prevention of excessive purinemia, for endogenous uric acid must always appear in the urine, and the removal of the results of toxemia from the organism as well.

Method of quantitative analysis for uric acid (Hopkins' method):

Add to 100 cc. of urine, ammonium chlorid to saturation (about 35 gm.), let stand for 2 hours, stirring at intervals. Filter through filter paper, and wash 3 or 4 times with saturated aqueous solution of ammonium chlorid. Wash off the precipitate with hot water. Measure the result, and for each 15 cc. add to the final result 1 mg. (there need never be more than 20 cc. or 30 cc.). Add excess of hydrochloric acid and heat just to boiling point. Let stand for 2 hours and filter. Wash precipitate with cold water. Then wash the precipitate with hot water to which sodium carbonate has been added. Make the quantity up to 100 cc. with the soda solution. Add 20 cc. pure sulfuric acid and titrate, agitating all the time, with $\frac{1}{10}$ normal potassium permanganate solution until pink color appears which remains permanent for an appreciable interval. Multiply the number of cubic centimeters of permanganate solution used by .00375 adding to the result 1 mg. for each 15 cc. of filtrate, as mentioned, and the result is the number of grams of uric acid in 100 cc. urine. If the urine is alkaline, precipitate phosphates by boiling and filter off before beginning the process.

The $\frac{1}{10}$ normal solution of potassium permanganate is made as follows: Dissolve 1.577 gm. potassium permanganate in 900 cc. distilled water. Place a portion of this solution in a buret and titrate against a decinormal solution of oxalic acid as follows: Take 10 cc. of the decinormal oxalic acid solution in a beaker, add some diluted sulfuric acid, and heat to 60° C. To this hot solution add the permanganate solution until faint pink color appears permanently. Note the number of cubic centimeters of permanganate solution used, and then dilute the remainder so that 20 cc. will exactly correspond to 10 cc. of the decinormal oxalic acid solution. Each cubic centimeter of the $\frac{1}{10}$ normal permanganate solution corresponds to .00375 gm. of uric acid. The permanganate solution usually retains its strength for several weeks, but should always be restandardized with oxalic acid before it is used.

The substance employed in this study is obtained from several species of *Salix* and *Populus* (nat. ord. *Salicaceae*), and is a decomposition product of the glucosid salicin (recognized as such as early as 1838 by Piria), saligenin in chemic combination with castaneotannic acid. Saligenin tannate is, therefore, a definite chemic substance. Over salicylic acid it presents the advantage that while equally efficacious, it does not disorder the digestion nor present untoward symptoms. It is preferable to the salicylates in that it is antiseptic, while the salicylates are not, and more readily splits up. Over both it offers the advantage of larger dose and longer period of administration. The dose is 1 gm. (15 gr.), twice or 3 times daily, after meals; *i. e.*, 2 gm. to 3 gm. (30 gr. to 45 gr.) each day.

CASE I.—O. W., November 12, 1902. Civil engineer. For many years the patient suffered from intestinal fermentation, angiospastic hemicrania, excitability of temper, emaciation, and long periods of disability from so-called neurasthenia. Urinary examination showed specific gravity 1.011, excess of indican (indoxyl), calcium oxalate crystals. Urea, 2.07%, morning; .183%, night; uric acid, .005, morning; and .01, night. November 26: Specific gravity, 1.012; indican, diminished; urea, 1.04%; uric acid, .0783; complete relief of symptoms of migraine. December 31: No return of symptoms as regards nervous or digestive system.

CASE II.—C. G., October 3, 1903. Lady. The patient had muscular pains, palpitation, dead-finger symptoms, persistent headaches. The urine shows specific gravity, 1.005-1.007; increased indican; urea, 1.04%, morning; 1.03%, night; increased amount of phosphates; uric acid, .001%, morning; .001%, night. October 20: specific gravity, 1.017-1.018; urea, 1.35%, morning; 1.80% night; uric acid, .004%, morning; .0046%, night. Total clearing up of symptoms.

CASE III.—E. P., November 20, 1902. Merchant. History of persistent headache, palpitation, cough, pains in back, uneven temper, loss of flesh, devoid of ambition. Urine, specific gravity, 1.022-1.024; trace of albumin; markedly increased indican; urea, 2.78%, morning; 2.28%, night; uric acid, .0055%, morning; .0023%, night. Many calcium oxalate and uric acid crystals in sediment. January 4, 1903: Specific gravity, 1.010; urea, 0.69%; uric acid, .04%; indican, normal; no crystalline sediment. The report was during a period of excessive fatigue. May 23: Specific gravity, 1.022-1.026; urea, 2.3%, morning; 1.5%, night; uric acid, .073%, morning; .053%, night. No disability since last report.

CASE IV.—Retired, F. D., October 1, 1902. History of palpitation, flushing, headaches, joint pains, "dyspepsia." Urine, specific gravity, 1.010; indican increased; urea, 1.20%; uric acid, .031%. No crystalline sediment. October 15: Specific gravity, 1.012; urea, 1.87%; uric acid, .014%. June 16, 1903: Specific gravity, 1.017; urea, 1.87%; uric acid, .0422%. Complete relief of symptoms.

CASE V.—H. F., November 11, 1902. Lawyer. History of joint and muscular pains, insomnia, general nervousness, anal pruritus. Urine, specific gravity, 1.024-1.025; greatly increased indican; few hyaline casts; calcium oxalate crystals; urea, 2.1%, morning; 2.13% night; uric acid, .052%, morning; .047%, night. December 29: Specific gravity, 1.018-1.026; indican normal; no casts; urea, 2.5%, morning; 2.08%, night; uric acid, .06%, morning; .08% night. February 22, 1903: Specific gravity, 1.026-1.032; urea, 2.30%, morning; 2.08%, night; uric acid, .01%, morning; .019%, night; many calcium oxalate crystals. Has had no medicine since January. June 12: Specific gravity, 1.018-1.020; urea, 2.10%, morning; 2.22%, night; uric acid, .081%, morning; .096%, night. Is now perfectly well.

CASE VI.—L. P. Civil engineer. January 14, 1903. History of intercostal neuralgia, anal pruritus, severe frontal headaches, muscular pains. Urine, specific gravity, 1.021-1.022; indican increased. Urea, 2.6% morning; 1.87%, night; uric acid, .007%, morning; .0044%, night. January 30: Specific gravity, 1.017; urea, 1.87%, morning; 1.66%, night; uric acid, .0358%, morning; .0395%, night. February 18: Specific gravity, 1.026-1.028; urea, 1.9%, morning; 1.83%, night; uric acid, .0795%, morning; .042%, night. March 30: Specific gravity, 1.014-1.020; urea, 1.04%, morning; 1.25%, night; uric acid, .0254%, morning; .0141%, night. June 15: Specific gravity, 1.020-1.022; urea, 1.77%, morning; 1.7%, night; uric acid, .044%, morning; .04%, night. Total absence of symptoms. November 12: Specific gravity, 1.018-1.020; urea, 1.35%, morning; 1.93%, night; uric acid, .046%, morning; .057%, night. Has taken no medicine since last report, and has continued well.

CASE VII.—M. H., lady. February 14, 1903. For many years the patient was the subject of membranous enteritis, successive attacks of pleurisy, numbness of hands and feet, persistent headaches. Urine, specific gravity, 1.010-1.015, lime oxalate crystals; urea, .72%, morning; 1.354%, night; uric acid, .028%, morning; .039%, night. March 29: Specific gravity, 1.010-1.015; urea, 1.25%, morning; 1.90%, night; uric acid, .0048%, morning; .0104%, night. June 9: Specific gravity, 1.014-1.018; urea, 1.7%, morning; 1.87%, night; uric acid, .0085%,

morning; .018%, night. All symptoms but those referable to the enteritis have disappeared. June 30: Specific gravity, 1.014-1.022; urea, 1.46%, morning; 2.19%, night; uric acid, .0065%, morning; .0185%, night. Patient remains well.

CASE VIII.—M. N., lady. January 20, 1903. History of joint pains for several years, dry eczemas of legs, palpitation, excruciating headaches. Has tried various baths with indifferent success. Urine, specific gravity, 1.010; increased indican; marked trace of peptones; urea, 1.48%, morning; 0.627%, night; uric acid, .036%, morning; .0029%, night. February 25: Specific gravity, 1.020-1.022; urea, 1.66%, morning; 1.7%, night; uric acid, .035%, morning; .0534%, night; eczema improved. April 20: Specific gravity, 1.014-1.016; peptones still present; urea, 1.05%, morning; 1.59%, night; uric acid, .0425%, morning; .035%, night. May 20: Specific gravity, 1.018-1.023; urea, 2.4%, morning; 2.6%, night; uric acid, .0425%, morning; .0497%, night. No headaches since last report. June 12: Specific gravity, 1.016-1.022; no peptones; urea, 2.08%, morning; 1.8%, night; uric acid, .0441%, morning; .0365%, night. No joint pains or other symptoms.

CASE IX.—G. E., lawyer. January 20, 1903: The patient suffered from pains in back of neck, lack of ambition, tarsalgia, is emaciated, and has been treated for malaria for several years. Urine, specific gravity, 1.010-1.018; largely increased indican; urea, 1.04%, morning; 2.08%, night; uric acid, .011%, morning; .0115%, night. February 23: Specific gravity, 1.022; indican still increased; urea, 1.66%, morning; 1.27%, night; uric acid, .0385%, morning; .031%, night. April 19: Specific gravity, 1.023-1.025; urea, 2.08%, morning; 2.28%, night; uric acid, .0535%, morning; .061%, night. August 17: Specific gravity, 1.018-1.019; urea, 1.9%, morning; 1.3%, night; uric acid, .047%, morning; .046%, night. November 19: Specific gravity, 1.016-1.020; urea, 1.04%, morning; 1.25%, night; uric acid, .031%, morning; .0375%, night. Patient has been well, and has taken no medicine since last report.

CASE X.—G. Q., merchant, December 13, 1902. Patient was formerly diabetic, a periodic sufferer from psoriasis, headaches, palpitation, insomnia. Urine, specific gravity 1.023-1.028; indican in large amount, calcium oxalate in abundance. Urea, 2.15%, morning; 1.97%, night. Uric acid, .03%, morning; .041%, night. January 14, 1903: Specific gravity, 1.022-1.028; urea, 2.13%, morning; 2.35%, night. Uric acid, .046%, morning; .072%, night; indican normal. Psoriasis has cleared up; all symptoms much improved.

CASE XI.—S. J., merchant, December 29, 1902. History of pains in back and leg muscles, numbness of thighs, frontal headaches, vertigo, insomnia. Urine, specific gravity, 1.022; urea, 1.02%; uric acid, .06%; many lime oxalate crystals. May 13, 1903: Specific gravity, 1.022. Urea, 1.57%; uric acid, .0031%; no crystalline sediment. May 31: Specific gravity, 1.022; urea, 1.87%; uric acid, .009%; phosphates markedly increased. Symptoms entirely relieved.

CASE XII.—T. W., broker, April 7, 1903. Vertigo, insomnia, numb hands, tinnitus aurium, headaches. Urine, specific gravity, 1.010; urea, .92%; uric acid, .02%; phosphates diminished. June 10: Specific gravity, 1.018; urea, 1.87%; uric acid, .07%; phosphates increased. Symptoms entirely relieved.

CASE XIII.—A. T., broker, April 10, 1903. History of "dyspepsia," constipation, headaches, numb and cold fingers, insomnia. Urine, specific gravity, 1.018; urea, 1.62%; uric acid, .08%; few hyaline casts. June 26: Specific gravity, 1.017; urea, 1.51%; uric acid, .075%. No hyaline casts. Still constipated, otherwise well.

CASE XIV.—W. N., merchant, March 6, 1903. The patient suffered from swollen feet, vertigo, occipital headaches, palpitation, insomnia, painful tendo-achillis, tarsalgia. Urine, specific gravity, 1.020; traces of albumin; urea, 1.02%; uric acid, .001%; diminished phosphates. May 11: Specific gravity, 1.020; no albumin; urea, 1.09%; uric acid, .03%; phosphates increased; no edema pedum; tendo-achillis still painful. June 26: Specific gravity, 1.014; urea, .83%; uric acid, .025%; phosphates normal. Symptoms markedly improved. Patient complains only of occasional headaches.

In all the cases reported various methods for relief of symptoms had been previously adopted without appreciable success. Those cited were difficult ones in which to expect complete relief. In all these patients there have been no relapses, so far as can be learned from an investigation carried on during the present month. To summarize this somewhat lengthy presentation of the subject:

1. The endogenous uric acid is the one chiefly concerned in gout and purinemia.
2. The uric, as well as phosphoric acid excretion, is merely an index of the amount of retrograde metamorphosis of the body nucleins.
3. Since the endogenous uric acid is independent of the presence of animal food in the diet, the patients should be limited only in quantity in order to reduce the intake to the needs of the organism.
4. The role of the liver in gout is purely a negative one, *i. e.*, its inability to act as a poison filter.

5. The keynote to the treatment lies in (1) limiting all toxic influences and formation of toxins, particularly in the alimentary canal, in order to minimize the retrograde metamorphosis of the body nucleins; (2) preventing the absorption of all toxic material; or (3) promoting the elimination of the products of toxic agents.

THE LIFE-STUDY OF PATIENTS, OR THE BIOGRAPHIC AND MULTIPLE BIOGRAPHIC METHOD OF DISCOVERING MEDICAL TRUTH.

BY

GEORGE M. GOULD, M.D.,

of Philadelphia.

Most physicians busy themselves with the single illness of which the patient presenting himself complains, and medical practice consists almost always of such treatment of the temporary and single complaint. The repetition of the affection at a later time is treated in the same way. There may be some vague connection noted by the physician between the two or more illnesses, but, at least in cities, the rapid elimination of the old-fashioned family physician, who attended one patient and family for a lifetime, is fast making even that poor overlook impossible.

Concurrent affections, and those of organs treated by specialists, were, moreover, not noticed, and a dozen symptoms of minor diseases were not thought of, or were listed as discrete, and without causal or related nexuses. If any physician rose to a philosophic gathering of the facts of his individual patient's several illnesses, he hardly succeeded in looking over the entire life, and subjecting the symptoms and diseases of the whole personality to a rigorous analysis and coordination.

Lastly, none has ever thought of bringing a large number of clinical life-histories into comparison and producing a composite photograph of the complete pathologic findings. And just this method, one would think, would have been early seized upon as that certain to bring to view medical truths otherwise remaining hidden from the observer. The method as applied to 14 patients with one disease, has yielded unexpected discoveries and demonstrated a unity of cause and of diverse symptoms that was wholly unforeseen.

If one glances through the biographies of any 25 great literary workers he will find a strange and striking difference between the personal lives of perhaps half of the number and the others. Twelve or 15 will be found to be comparatively healthy, while the others are constantly afflicted with much suffering. In some cases their physical diseases will result in the profoundest tragedies. Thus Gladstone, Goethe, Taine, Kant, Mommsen, Gibbon, Zola, Verdi, Agassiz, Fiske, Longfellow, Lowell, Hawthorne, etc., leading sedentary and scholarly lives, possess good health, while we find that other men of the same callings and application to literature or science, endure lives of intense suffering. Of this class are George Eliot, Huxley, De Quincey, the Carlyles, Parkman, Browning, Wagner, Spencer, Whitier, Margaret Fuller, Lewes, Darwin, Nietzsche, etc. The attitude of the world, even of the medical profession, in the presence of disease has been one of fatalism. Indeed, the belief in fate, one may surmise, has been largely due to the strange and mysterious incidence of disease. Why one should be sick and another free from sickness has struck men's minds ever since the riddle of life worried the soul of the boil-pestered Job. So long as the physician was concerned with his patient's single and passing (or killing) ailment, he gained no large overlook to bring unity into the pathologic problem of a whole life, or of a number of lives. And viewing disease as an objective entity, studying it from the standpoint of morbidity, infectious or organic, does not yield the same results as

in viewing it from the aspect of the patient, the whole life of the patient, and the whole lives of many patients. Take the 14 mentioned: If one physician could have treated all of them during their entire lives he would undoubtedly have seen that there was some single underlying unity and cause for all their afflictions. But as the single complaint was treated at one time by one, or even several physicians, and as a hundred were consulted during their lives, all the cases remained discrete, mysterious, and utterly inexplicable. Moreover, looking into the minds of their physicians we find that not one had any conception whatever of the cause and nature of their patients' maladies, and not one agreed with the other as to treatment. A peculiarly instructive fact is also this: Many symptoms complained of by these patients were held by both patient and doctor to be merely accidental and concurrent, which were repeated in other cases, and which were, in fact, bound by a single cause into a strictly pathologic unity. By the method of focusing the clinical life and a number of clinical biographies into a composite whole, new truths at once break upon the observer which were necessarily hidden from the physician of the single day or year, of the single disease, of the single patient, and of the single life.

And the method is by no means of value only as to migraine or eyestrain; it will prove, I suspect, to have equally good results in other diseases. The study of clinical biographies will prove as illuminating in the etiology, cure, and prevention of many diseases, even in those in which we think all mysteries are explained by bacteriology, histology, or other objective methods. Just as the good physician treats his patient and not the disease, so general pathology needs to study the patient instead of, or at least in addition to, his disease. The sick man rather than the man's sickness, his life rather than his single illness, many lives instead of one—that is a method of eliciting medical truth which needs exploiting, and which will in the future bring unexpected light into our pathologic darkness.

In addition, I am sure that the results of eyestrain which I have discovered in clinical biographies are by no means all. In private practice I have gained glimpses too indefinite as yet to put on record, of further and possibly of as great influences of ocular malfunction in causing other morbid functions, or in influencing them. No truth is more certain in general biology than that long and oft-repeated function begets structure. Inevitably, therefore, functional morbidity must produce organic or structural morbidity. In illustration of that thesis lies much of the progress of future medicine. The study and systematization of long and repetitive malfunction can be made only by means of the method of biographic clinics. That study largely lies in the hands of the family physician, when he will rise to his opportunity.

Our first surprise in these 14 biographic studies is that there have been so many sufferers. Without any extended search, and merely incidentally, I have, in all, found nearly a score of literary, scientific, or musical geniuses who were hardly suspected of having been so grievously afflicted. In their biographies were also allusions to many of their friends or distant contemporaries patiently enduring the insults of the same disease. And when one looks into the history of the disease as chronicled in medical literature, it is plain that from the earliest barbarism to the latest civilization a large portion of humanity has had the same disease. In medical practice the physician finds all over the world the malady tremendously prevalent and rapidly growing more frequent, and more terrible in its life-wrecking consequences. One's amazement is beyond expression when, lastly, it is found that this disease of untold millions of the past and of others now living, is a confessed mystery to science. Its very name is an absurdity—the non-naming of a trivial symptom, generally not present, of a disease, the very organs affected being unknown, the symptoms indescribable, the cause unknown, the nature

unknown, and all treatment absolutely resultless. This bizarre condition of scientific impotence is rendered still more farcical by the fact that, except in one case, not a patient of the 14, nor a physician of their hundreds, recognized the disease before them. They were utterly mystified, and did not even call it by any name. Even Nietzsche argued with his physicians that his terrible disease was not one-sided or hemispheric.

The fact of the extreme diversity of the symptoms of the 14 patients, of itself prevented their physicians from recognizing the single cause to which they were due. The nearest they came to it was a half-glimpsed, vague, and passing adumbration of the truth. It was in part a sort of flattery of the patient, usually by himself originally, that begot the theory that brain working caused suffering. The hundreds of columns of twaddle about "brain-fag" in the London and American newspapers in October, November, and December, of 1903, show the existence of the same superstition. A thousand brain workers have "brain-fag," but another thousand do not. It is plain that the explanation is badly in need of explanation. Intellectual work does not produce disease or suffering any more than muscle work. Evolution has made no such stupid blundering as that.

But muscle work with organically diseased muscles or blood-making organs does produce trouble, and just so brain work with morbid nervous organs may, and must beget morbid results. The physicians of our 14 patients never once asked if any of the organs put to such frightful labor by the intellect were abnormal. The study of the biographic clinics of these patients at once shows that the greatest, most delicate, most complex, most intellectual sense organ is, in literary activity, put to the greatest labor. Physiology long since demonstrated that in a large number of these eyes, their anatomy is imperfect, their function pathogenetic. The old truth will never be sufficiently well learned that morbid physiology is the source of pathology, that malfunction precedes and begets organic disease. This is forgotten in the avid study of the end-products of disease, and of the disease itself instead of the diseased patient.

The great error that intellectual or literary work *per se* produced the diseases of our 14 patients resulted in the rule of life, learned from experience, or half-taught by the desperate physician, to get into the open air. Thus these patients found it wise to "take a trip to Switzerland," "to go to Italy," "to walk the moors," "to take a vacation," "to run down to the Riviera," "to climb mountains," "to go on a jaunt to the seashore," etc. Often the greater part of patients' lives was spent in this way. The success of this empiric therapeutics was undoubted, but only so long as the out-of-door life was continued. With the return to sedentary life the old troubles at once resumed their sway. We now know that eye work, not intellectual labor, was the cause of the disease. But a thousand articles and books on "migraine" written during 300 years, came only so near the truth as the suggestion that "migraine" affects chiefly the educated and intellectual classes. And even this statement is not true, because it affects all eye workers in equal degree, whether they are readers, thinkers, litterateurs, etc., or simply sewing women, typewriters, and handicraft laborers. The fact suggests that with the older physicians their well-to-do patients were their chief concern, and the poor were relatively ignored. But the poor have the aristocratic disease just as frequently—if they use their eyes within reading and writing distance as incessantly as the students. The presence of astigmatism has nothing to do with the social or intellectual status, although it had much to do with the physicians' reports of cases, etc. The walking cure, as it may be called, was learned by bitter experience and usually by the patient himself without the assenting advice of the puzzled doctor, who did not know what else to do.

Note, however, that in the thousand books and articles

on "migraine" the walking cure is not laid down as any part of the scientific treatment. The biographic clinic alone teaches that lesson.

The demand of the tormented system for walking and physical exercise is in astonishing evidence in the lives of nearly every one of the 14 patients studied. It undoubtedly dictated the *Beagle* and the *Rattlesnake* voyages of Darwin and Huxley, it drove Parkman to a fury of athleticism that was ruinous, and was the direct cause of the aphorism style of Nietzsche. In every one it took a peculiar coloring, but move they must or they would have gone mad, as Wagner said of himself.

The clearest medical advice to the migrainous "brain worker," the "brain-befagged," the "neurasthenic," etc., was that the stomach and digestion were at fault. Diet became the will-o'-the-wisp, which engendered a thousand cookery books, systems of diet, food rules, fads, institutions, cures, and crankeries, in reference to eating and drinking. All Europe seemed largely ordered by the needs of patients worshipping or bringing offerings of time, wealth, and lives themselves, to the altar of the great god Dyspepsia. All this was because in a certain, or uncertain, proportion of cases the digestion was less or more disordered by "migraine." No one has ever agreed with another as to what constitutes the symptoms of the disease migraine, but some migrainous sufferers have nausea and vomiting or other dyspeptic symptoms. That the superstition that these secondary gastric symptoms are primary and causative still rules the lay and professional mind, is demonstrated in every textbook and article written on the subject. The hundreds of brain-fagging, "brain-fag" correspondents of newspapers of the last few months show how living is the old idolatry.

"Migraine" and "brain-fag" are caused by astigmatism, but eyestrain causes many other morbid symptoms than those grouped under the nonsignifying and misleading terms. In no textbook on diseases of the stomach or of the digestive organs will one ever find a word as to eyestrain, and yet eyestrain possibly causes more of the diseases of digestion than all other causes combined. The study of the patients' single disease, or of the disease itself, would never have revealed this truth. Only the life-histories of the suffering patients make the fact apparent.

It is noteworthy how frequently proverbial and empiric wisdom forefelt the lessons here emphasized. One of Lincoln's maxims was, "Keep your digestion good; steer clear of the biliousness." Sir Benjamin Ward Richardson said that the would-be centenarian among other things should "work as little as possible by artificial light." Von Moltke, Sir James Sawyer, and many others, have advised strongly, regular out-of-door exercise. Dr. Diet, Dr. Quiet, and Dr. Merryman, are old and famous physicians. The existence of the large number of spas, health establishments and resorts, cures, hydropathic institutions, sanitariums, and the periodic migrations to Italy, Switzerland, and sunny climes where out-of-door life is encouraged, are all to some extent the products of eyestrain.

Most suggestive is the fact that these establishments, whether frivolous and fashionable, or scientific and curative, are based upon a regime which stops near use of the eyes. How fashion does this, need not be set forth. Take the best instance of the best class of these "waters" or "cures"—Carlsbad. In the first place the old superstition that there is anything mysteriously or miraculously therapeutic in the water itself is worthy of the days of opera bouffe, and it is far more wonderful that the humbuggery has been accepted by the world, lay and medical, so long. If one, any place in the world, will dissolve 15 grains of sodium bicarbonate and 25 grains of sodium sulfate in a pint of water, it would have all the therapeutic value of the Carlsbad spring. Add some citrate of lithia, and it would be far better than any spring water yet discovered. The cunning commer-

cialism that sells water, the commonest thing in the world, at the price of wine, will probably not be extinct for centuries to come. That is the sugar of milk placebo which fixes the attention, while several other really important things are demanded with military authority: 1. A diet which lessens the stored energy of the organism. 2. Baths and other measures which increase metabolism. 3. An amount of walking and exercise that increases the outgo of force in normal or physiologic methods.

But note the ignored and revelatory fact implied in all this: All three methods reduce the excess or overstock of fat and nervous energy which is the basis of "gout," etc., but while they do this they absolutely prevent near use of the eyes. The "walking cure," the rest-of-the-eyes cure, that every poor eyestrain and migrainous patient has found by bitter experience so necessary, is the *sine qua non* at Carlsbad. This is the way it is described by Henry Cunningham, C.B., in the *Nineteenth Century* for December:

So far as watering places are concerned, the only reason why they appear useful is that when a man goes there he is free from business, letters, etc.

The grounds belong to the town and are laid out in walks which extend over nearly 10 square miles of country. Along these walks in fair weather and in foul, in broiling sun or in drizzling rain, the wretched patient is compelled to toil. Up hill and down hill he must go, and the more up hill the better, until a pedometer in his pocket shows that he has walked 24,000 steps daily.

The diseases of eyestrain all show an excess of nervous energy, and all are dependent upon near use of the eyes. All are cured by draining off the excess of innervation through physiologic channels (walking, athletics, etc.), and stopping near use of the eyes. It is most suggestive and noteworthy that what cures "gout" cures the hundred sequels of eyestrain—and vice versa!

Eyestrain has a peculiar and powerful irritant action upon the nervous system. It begets a hundred differing results according to the nature, needs, and necessities of the individual, but all are summarized as an excess of innervation. Hence the demand of the organism for relief from the morbid stimulus, and for an outlet of the overflow by means of muscular action. Thousands of quotations could be adduced to show this. In addition to the two reasons given above, the eyes demand that (partial) rest only to be secured by the cessation of "near work," such as is gained in walking, etc.

All the treatises on migraine have failed to note this fact or its philosophy, and yet it is a symptom that is most characterizing and significant. It often governs the life, and makes or mars fortunes and dispositions. Upon it turns the whole success or failure of ambitions, and it surely colors and controls the quality of literary works as none other. This is at once manifest in the study of nearly all of our 14 patients, and daily stands plain in the confessions of patients in the physician's office. It engendered a state of excitement and tension in them which had an injurious effect on personal character, and on the matter, style, and judgment of their writings. This is painfully evident in most of the 14, but rises to positive morbidity in Carlyle, Wagner, and to ruinous extremes in Nietzsche.

It is impossible, says George Eliot, for strong, healthy people to understand the way in which malaise (her euphemism for sickheadache) and suffering eat at the roots of one's life. It is at first sight strange that eyestrain may produce in some patients sleepiness, dulness, etc.—pure inhibitory effects, while in others the nervous system may be driven to a fury of irritation. Thus in the cases of George Eliot, Whittier, and Darwin, there was the most painful lassitude and exhaustion, while in Carlyle, Wagner, Nietzsche, etc., there was a morbid hyperesthesia and activity. Often both conditions may alternate in one patient. Although George Eliot was usually dejected, depressed, and tired, she speaks of "the excitement of writing," and the mechanism is

seen in many sentences as, "My idle brain needs lashing." In Wagner, eye work usually produced feverish intensity and irritability, and yet he says, "Sometimes I stare at my paper for days together." But it is true, as he says, that exaltation was the rule and ordinary calm abnormal. Hundreds of poignant quotations would vividly demonstrate this. In the same way Carlyle had to work with his "nerves in a kind of blaze," "in a red hot element," "with his heart's blood in a state of fevered tension," "in a shivering precipitancy," etc., and yet sometimes it was inhibition instead of hyperesthesia, and he sat at his desk, stared at his paper, his imagination would not work, etc. Writing stirred Mrs. Carlyle's head to "promiscuousness," and always finally exhausted her. It "stirred up" Parkman's head, produced "a highly irritable organism," and he stopped to avoid greater troubles, as did also Spencer. But in Nietzsche it drove the sufferer to "a horrible earnestness," "a nervous excitability," "an unendurable *spannung*," "a subterranean fire," etc. To use his own words, "The vehemence of the interior vibrations was frightful." It drove Darwin to the sandwalk and De Quincey to opium. In almost all it produced melancholy, helplessness, and despair; made physicians think Parkman and Wagner and Nietzsche were insane, made several believe death was at hand, begot the resolve of suicide in Wagner, and directly caused the cerebral paralysis of Nietzsche. With the biographic overlook one realizes that this hyperexcitation and torment of the nervous system caused by eyestrain, demonstrates a causal unity of the whole consequences of athleticism, walking, dieting, touring, hydropathizing, irritability, diseased literature, melancholia, pessimism, and general morbidity.

Colds, influenzas, etc., are not alluded to in the treatises on migraine, and it is only by the study of the life-records of migrainous patients that the truth becomes manifest that inflammations of the mucous membrane of the upper respiratory organs are often caused by eyestrain. In the individual illness or even individual patient, the relation is overlooked. Like a dozen other diseases, the common cold or grip is looked upon as a stroke of fate, and to be accepted without curiosity as to cause. But even a crude science is finally driven to the supposition of a nondiscovered cause mysteriously at work. Whatever role the microorganism may play, the "soil" (as always) must be prepared. All rhinologists now admit that some mysterious cause is at work. One great physician writes of colds and influenzas that "they may be due to microorganisms, or local conditions in the air passages, but these maladies, as we now know, both depend to some extent on a special predisposition in the sufferer, having its root in the nervous system, and both leave their stamp on that system and gradually undermine it." And only biographic clinics show that eyestrain is one of these frequent "special predispositions of the nervous system." The seemingly illogic incidence of these inflammations of the mucosa in some patients, and the escape of others, is, at least in part, explained by the fact that when the ocular reflex expends itself continuously on one set of organs, especially those of the digestive system, other organs are freed from the attacks. Thus Carlyle, Huxley, Margaret Fuller, and Darwin have no colds, De Quincey but few, Whittier, Lewes, and Browning, more. Wagner saw some connection when he wrote, "my catarrh has developed so that I may hope it will rid me of my usual winter illness." Nietzsche was tormented with colds, hoarseness, etc., all his life, and Mrs. Carlyle and George Eliot seemed never to have been without influenza, grippe, sore throat, etc. In private practice the relation of influenza, colds, etc., to eyestrain, has often been noticed. Colds alternating with the other symptoms, freedom from the one set replacing suffering from the other, has been noticed. And colds, also, as a terminal affection, *i. e.*, upon the more permanent disappear-

ance of other symptoms, are especially noteworthy. George Eliot's only disease on the day of her death was supposed to be laryngeal sore throat. Lewes also died a day or two after taking cold."

After I had several times noticed the strange manifestation of peculiar and unaccountable eczemas, rashes, etc., as the terminal stages of ocular headaches and of sickheadaches, I found in the reports of some old physicians a clear statement that "herpetisms" were sometimes reported as the sequels of migraine. Modern authors treating of migraine know nothing about this. Wagner had repeated attacks of a "cutaneous malady," and "continuous attacks of erysipelas" which tormented him much of his life. I remember especially one patient who had most distressing attacks of "hives," and various other eruptions, pronounced by the best dermatologists atypical, and which were puzzling to them, and intractable. These attacks were sometimes called acute urticaria, psoriasis, generalized eczema, pityriasis rosacea, etc. In looking back over her life, this very intelligent patient now remembers that the eruptions were always connected with extreme use of the eyes, headache, and especially sickheadache. All of these symptoms in her case have since been repeatedly demonstrated to be due to eyestrain. They recur with leaving off the glasses, and are relieved at once by proper correction of the eye defect. Since the above was written, a most carefully observed and excellently reported case has been called to my attention. It was in the practice of Dr. Charles A. Oliver, and published in *The Philadelphia Medical Journal*. The repeated demonstrations that the urticaria was absolutely caused by eyestrain is most convincing. Observations would doubtless prove the sequel more frequent than is supposed.

Older authors writing of migraine also emphasize the fact that pareses, partial paralyses, anesthetics, disorders of sensation, etc., are frequently complained of by patients suffering from migraine. The most common of these symptoms appear to be paresis, numbness, and tingling (as of "pins and needles") of the hands and arms, extending to the neck and throat, with temporary loss of speech and confusion of ideas. Nietzsche, Wagner, Mrs. Carlyle and others, had similar symptoms, called "rheumatism" by biographers, patients, and physicians. One wonders how many such patients have suffered from such "rheumatisms." There is not a little mystery about the "gout" of Lewes and about Parkman's life-long articular trouble and lameness.

There is one important symptom of migraine that has almost universally been omitted by the writers of textbooks, but which is present in almost every case of the disease, and in all cases of severe eyestrain. This is insomnia. Every one of the 14 patients whose cases are reported in *Biographic Clinics* complained of it bitterly, and of most the inability to sleep was the chief of all complaints. In the case of the individual illness of a single patient the physician overlooks the symptom; in the life-histories it appears with pitiful reiteration.

There is one other symptom often alluded to by the patients of biographic clinics, which is frequently spoken of by patients in the oculist's office. Beside all those complaints that can be named or described, there is a nameless and indescribable suffering that often afflicts them as powerfully as the localizable and describable ones. They tell you they cannot tell how they suffer, nor where. It is "dreadful," "horrible," "inexpressible," etc., and it is real. That is all they can say.

According to the older conceptions, migraine was an absurd name of a trivial symptom, not generally present, of a disease beginning with the trephining savages of barbarism, widely prevalent in all human history, and vastly increased both in severity and numbers attacked by every advance in civilization. It is today wrecking millions of lives and ambitions, often making of them tragedies of needless suffering. The cause and nature of the disease is utterly unknown, and even its location, or

the organs in which it is seated, are also unknown. The very symptoms are indescribable, and reporters and writers differ greatly as to what they are. There is no treatment whatever that cures, none that even relieves. Thus the profession stands today impotent before its opprobrium, and despairing of resolving the mystery, has turned its back upon it, eager only to explain some organic or infectious disease that does not cause a hundredth of the suffering that is due to migraine.

And yet a glance at the actual and entire life of migrainous patients, and especially of several such lives, would at once have revealed the secret. Few cases, or perhaps no cases of the disease ever occurred except as a consequence of near use of astigmatic eyes, and every case is curable or at least preventable by proper spectacles.

It goes without saying that in the organism wrecked by a life of suffering, all reaction is killed; such cases, however rare, exist, and cure of them is impossible. But even in them some alleviation or change of symptoms is wrought by proper glasses. There is also, rarely, a habit of disease which is hard to break up, although in migraine it is usually to be construed as an unconscious confession of lack of skill in refraction. Migrainous diseases are especially easily controlled and are almost always extinguished even in the most severe and long-continued instances.

Moreover migraine is only one of the many results of eyestrain. The word should indeed be abolished, as it is utterly meaningless. Its two chief symptoms are headache and sickheadache, and these words should be used instead of migraine. When such symptoms are caused by evident organic, local, or systemic disease, there can be no mistake in the diagnosis. Yet even in such cases the pseudoeystrein symptoms, and also in the so-called "mimicries" of eyestrain, scientific spectacles will probably produce an alleviation or modification of the symptoms that is most noteworthy.¹

The continuance of all migrainous or eyestrain diseases indeed emphasizes the great need I have previously urged² of a systematic and periodic reexamination by scientific specialists, of the bodily organs and functions throughout life. Apart from the objective scientific value of such tests, they would often reveal, and thus prevent further ingravescence of pathologic conditions and trends, of profound value to individuals and families.

MORTON'S PAINFUL DISEASE OF THE TOES.³

BY

WALTER G. STERN, M.D.,

of Cleveland, O.

Orthopedic Surgeon to Mt. Sinai Hospital of Cleveland, O.

I have no accurate means of determining the relative frequency of Morton's painful disease of the toes. It is generally held to be a rather rare condition, denied by some writers, namely the French; but frequently described and insisted on by the Americans. The statements of the patients themselves have led me to suspect that there exist innumerable cases hidden away, only known to their fellows through the secret bond of their sufferings. One patient once said that if I would cure her sufferings without cutting, she could bring to my office 25 other "fellow shoe pullers," as she called them, of whom she had learned either from their voluntary

¹ But it must be remembered that the vast majority of so-called refractions is worthless. In Europe all refraction may be said to be unscientific, inaccurate, and without power to cure the symptoms and sequels of eyestrain. If attempted by objective methods alone, if done without a mydriatic in those under 50, if anisometropia is ignored, if the most absolute accuracy is not secured in estimating the least astigmatism, etc., the work is without therapeutic value. There are at least 68 reasons why glasses may prove incapable of curing the diseases caused by eyestrain.

³ Read before the Cleveland Academy of Medicine, April, 1903.

statements as to their sufferings or by seeing them pull off their shoes in her presence. The lack of information, which our profession in general holds about this most painful affliction, might tend to prove this particular trouble to be quite rare; yet few of my cases had been properly diagnosed by those who had been previously consulted. Shoe salesmen, by no means an unintelligent class of men, differ in their knowledge as to the existence or frequency of Morton's painful toe according to the locality of their business and the class of their trade. The shoedealers of the outskirts, the poorer communities, or the streets devoted to a cheaper class of trade, never hear of it. The sellers of the advertised

Fig. 1, Case I.—Exposure five seconds.

(\$3.50) brands and the large stores see it relatively infrequently. The salesmen in the exclusive and high-priced stores say it is quite a common condition in their patrons; while the custom shoemakers who make expensive shoes to order (at prices say from \$12.00 to \$30.00) tell me that next to corns, bunions and flat-foot, Morton's painful toe is the most common ailment calling for specially formed shoes. Together with the analysis of the literature on the subject, my own experience has led me to believe that this particular disease is the property and privilege of the comparatively well-to-do and is quite frequent among them; while the poor who comprise the bulk of our society, and who, by the way, do not usually indulge in narrow, thin-soled, uncomfortable shoes, are rarely afflicted.

In 1876, Dr. T. G. Morton, of Philadelphia, first called attention to an affection of the feet accompanied by no evident external changes, but characterized by extraordinarily severe paroxysms of pain radiating upward upon the dorsum of the foot, the paroxysms usually originating in the fourth metatarsophalangeal articulation. The pain may, however, affect the other joints. Dr. Morton conceived the idea that the external plantar nerve sent branches which wound about the necks of the metatarsal bones, and that the head of the fifth metatarsal impinged upon the neck of the fourth, and the head of the fourth upon the neck of the third, and thus pinched the nerve branches and caused the frightful neuralgia. His argument was further substantiated by the peculiar conformation of the arches of the foot, which makes the fourth metatarsal bone the most movable of all the metatarsals, and thus a trauma or a tight shoe might, in a favorable subject, cause these pains. The only treatment possible founded upon such pathologic grounds was the resection or excision of the fourth metatarsal bone. This he did with successful result in 15 patients, 13 females and 2 males; "all of the patients were surrounded, not only by the comforts, but in most cases the luxuries of life." Since the publication of this article, numerous cases have been reported

and many able writers have vied with each other to give a simple and sufficient explanation of these cramp-like pains, radiating out from the metatarsal phalangeal joints. It is not the purport of this paper to enter into this very interesting discussion, yet I will not refrain from presenting the three most widely disseminated theories.

1. The modern French school absolutely denies the existence of Morton's disease as a pathologic entity, claiming that the pain is always due to fracture, periostitis, clavus, tuberculosis, trauma, syphilis, etc., of which diseases the paroxysms are, therefore, only a symptom. The evidence of the American and English orthopedic surgeons is, however, in preponderance, and in this particular case the French more than the Germans have either not read or have paid no attention to the writings of the American surgeons. The Röntgen ray photograph in Case I (Fig. 1), clearly shows that at least in this one case, the fearful suffering was not caused by any local disease in and about the head of the fourth metatarsal bone.

2. Morton's theory as to the pathology and active causes has already been mentioned, but his observations have not been confirmed by later observers. A. E. Halstead, after studying the feet of 20 cadavers, concluded that the heads of the fourth and fifth metatarsal bones do not occupy the position that Morton claims in respect to the other metatarsals; nor can their heads impinge upon the necks of their neighbors, nor, finally, does the external plantar nerve give off any large branches which wind about the head, or rather, neck of the bone; but rather such branches run beneath the bones lying just upon the dense plantar fascia.

3. The view which I believe is universally admitted today, takes the stand that Morton's disease is purely a static condition of the transverse arch of the foot, quite analogous to flat-foot. The metatarsal and phalangeal bones of the foot form a transverse arch with the convexity upward, and the third and fourth metatarsal bones are at the highest point of the arch. Normally, when we step on the ball of the foot, the arch tends to flatten out under the weight of the body; but the elas-

ticity of its ligamentous structures—the transverse ligament, the transversalis muscle, the tendons of the peroneus longus and tibialis posticus and the plantar fascia—prevents the heads of the metatarsals from sinking down far enough to press upon the ground. If, however, the foot be subjected to a severe trauma or a weakening from long illness, or becomes overburdened by rapid increase in body-weight, so that the ligaments cannot hold the anterior arch in its normal condition, but permit the heads of the bones to press against the sole, the anatomic foundation for this disease is laid. Quite analogous to flat-foot, which is a sinking of the longitudinal arch of the foot, combined with external rotation,

this condition need not always be painful. Dr. Royal Whitman contends that the pain may be caused solely, or in great measure, by a pinching of the sunken arch by ill-fitting shoes. Reasoning from the arch of the hand, he finds that when we arch our knuckles and then pinch the entire hand (Fig. 2), we elicit no pain; obliterate the arch by hyperextending the fingers, or if one finger be held further back than the others (Fig. 3), and then pinch the hand from side to side, one experiences a pain radiating outward from the third and fourth metacarpal bones quite similar to that which occurs in

Morton's disease. We also often find a subluxation of the metatarsal bones which can be reduced with a snap. The success of the treatment instituted by Whitman and

Fig. 4.

Fig. 5.

Fig. 4.—Plaster cast of foot showing anterior transverse arch and reentrant angle of Goldthwaite.

Fig. 5, Case X.—Imprint of sole showing obliteration of the reentrant angle of Goldthwaite, the head of the second metatarsal bone touches ground while the head of the first does not.

Goldthwaite, based on this pathology, is a strong argument of its probability. At any rate, Morton's painful toe is a painful static condition and deformity of the foot with a definite pathology, analogous to painful flat-foot and caused by the breaking up or flattening of the anterior transverse arch of the foot. It is in itself a clinical surgical entity, and whatever painful conditions may arise from other surgical or medical diseases of the feet, these latter are not to be confounded with Morton's disease.

Almost all patients suffering from this affliction will be found to belong to the better and wealthier classes. Very few have sedentary occupations, many have grown stout within a short recent period of time, while in almost all instances careful questioning will elicit the history of a severe trauma shortly before the pain first came on; runaway accidents, jumping into the saddle, football, mountain climbing, tennis, and the like, are repeatedly given as the causative agent of the trauma.

The symptoms are a sudden feeling of uncomfortableness in the ball of the foot often accompanied by a snapping in the afflicted toe; then an intense, agonizing, burning, unendurable pain radiating from the fourth metatarsal head (it may however be any other, but usually the fourth) through the thickness of the foot up upon the dorsum, followed often by faintness, cold sweats and a total incapacity for the time being of directing the mind to any other subject. The patient is usually seized with an insane desire to remove his shoes no matter where he may be; he seizes a stick, a cane, or umbrella and jabs at the offending member so that he may get

relief through the counterirritation; he grasps his toe and tries to pull it out of joint, pinches the ball of the foot as though to reform the arch or he may overflex (sometimes, however, overextend) the toes, and so with a snap or grinding sensation ends the terrible agony which has been fancifully described by the sufferers as "tooth-ache in the toe," "angina pectoris of the feet," "piercing by red hot iron," etc. At first the pain only comes on while the patient is wearing shoes, or is subjecting the foot to the various blows and shocks which invariably accompany locomotion, but after years the cramp may come on even at night or while the patient is walking about barefooted. The pain may last from 1 to 48 hours and vanish as suddenly as it began. Another pathognomonic feature of this disease is the insane desire to remove the shoe regardless of the surroundings whenever a paroxysm of pain comes on. This is often the way patients make the acquaintance of fellow sufferers.

Upon examination one rarely finds the patients showing any stigma of nervous degeneration, they are for the most part well-nourished people of a rather Spartan fortitude. The feet are generally large and especially broad across the ball of the toes; but rarely do they show signs of flat-foot. The fourth or afflicted metatarsophalangeal joint is painful to pressure, but never swollen or reddened; it is always freely movable and at times subluxated. The ball of the toes, that is, the transverse arch of the metatarsal heads and the underlying cushion of fat, is flatter on the ground than normal and the usual depression between the big and third toes, called by Goldthwaite the reentrant angle of the foot, (Fig. 4) is usually obliterated as can be demonstrated by a plaster impression or a foot-print with printers' ink (Fig. 5). Wellmarked evidences of wearing tight shoes are usually to be found and not infrequently a callus may be discovered beneath the heads of the third or fourth metatarsal bones where the sole receives the undue pressure from the sunken metatarsals. The affliction may also be an hereditary one; a pathologic explanation of this has never been made. Of all cases, 75% are among women usually of middle life, but some cases have occurred in childhood.

The treatment proposed by Morton was the excision of the afflicted joint, but the later authors seek to restore the foot to its normal condition, and, therefore, use mechanical aid to reform the flattened anterior arch much as we do to correct the arch of flat-foot. The

insole devised by Whitman is most useful. It is much like the ordinary steel support for flat-foot, only it extends out to the toes, and has a transversely raised arch just where the ball of the foot presses upon it, thus arching the foot upward while walking. (Fig. 2.) To find the proper amount of convexity and to hollow this arch out just to avoid the callus is often a matter of the greatest nicety. In milder cases an adhesive plaster bandage around the ball of the foot will restore the arch (Fig. 1). Japanese stockings, Spanish lasts with convex soles, or pads of soft rubber in the sole of the shoe suffice. I propose, in my future cases, to fasten pads of soft rubber to a flat German silver insole to give a much-needed elasticity not found in Whitman's plates. Intractable cases can often be relieved only by means of incision.

Fig. 6, Case X.

CASE I.—Mrs. K., aged 49.

Family History.—No nervous disease in family.

Personal History.—About 14 years ago, while riding in a carriage, she had a severe accident. She sustained numerous bruises to the body, one eye was almost knocked out, and both ankles were sprained. Twelve years ago she noticed slight pain in her feet, especially after purchasing a new pair of shoes, but this pain soon left her and for the next three years did not return. Nine years ago, after wearing an unusually tight and high-heeled shoe, she experienced a sudden severe pain in the fourth toe of each foot, which has steadily increased in severity and duration. The paroxysms now come on night and day; they are worse when she has her shoes on. Heat seems to make the attacks more severe. The pain is a frightful burning stab accompanied with an intense neuralgic radiation on the dorsum of the foot. She pulls off her shoes no matter where she is; when she goes to the theater she carries with her a large pair of knit slippers, and when she is down town shopping she always waits for the car or her carriage in a secluded spot. She digs at the toe with a cane or umbrella to relieve the intense sufferings.

Examination.—Patient is a large, well-nourished woman, without the slightest tendency toward nervousness. Examination is entirely negative, except for the feet, which are especially

not pull off her shoe, but thumps her feet with her crutches. The paroxysms of pain often occur at night. She claims that her mother has an occult influence over this pain, and can cause it by approaching to within 20 feet of her.

Examination.—She talks and acts like a typical hysteric old maid, and the attending neurologist assures me she is such. No examination was made of the nervous system. The foot is large, and shows marked signs of having been badly abused by tight and pointed shoes and high heels. No flat-foot. The third metatarsal head of either foot is very sensitive to pressure, no thickening, no inflamed joints. Pressure from side to side causes paroxysms of pain. A broad shoe with a Spanish sole, and built on orthopedic lines was ordered. Three months later she was almost free from pain, and could walk several miles. Her mother cannot influence (or as she says "hypnotize") the foot through her new shoes as she could through the old ones!

CASE III.—H. M., male, aged 20.

Family History.—Negative.

Personal History.—He had a peculiar, chubby foot ever since birth, for which he was treated in childhood. For the past 3 years there has been a hard spot in the sole of the foot, which causes him severe paroxysms of pain, and prevents him from walking much.

Physical examination was negative, except for the condition of the right foot, which presents a slight congenital pes cavus. The first 3 toes are overextended on account of the shortening of the extensor tendons. The instep is very high. The anterior arch is broken down and the second and third metatarsal bones are the lowest in the arch. Under the heads of the second and third metatarsal bones is a small painful callus, caused by the weight of the body being borne by these two bones instead of the metatarsal of the great toe. The third metatarsophalangeal joint can be subluxated and the pressure on the foot from side to side causes severe paroxysms of pain. I advised extensive operating to correct the deformity, etc., but treatment was refused.

Note.—I include this case as one of Morton's disease, because it is essentially a breaking down of the anterior transverse arch of the foot—from malformation instead of the usual trauma—and because such breaking down has set up peculiar radiating pains coming on in paroxysms.

CASE IV.—Mrs. S., aged 28.

Family History.—There are several cases of tuberculosis in the family.

Personal History.—She has always worn tight shoes and high heels. For some years past she has suffered severely from paroxysms of pain radiating out from the third and fourth metatarsal bones of the right foot. When these pains come on she has often to pull off her shoe and stamp her foot to relieve it. Ice-baths moderate the pain.

Examination negative, except that the feet show very marked signs of having been abused by tight shoes. The ball of the right foot is flatter and a little broader than the left. The third and fourth right metatarsophalangeal articulations are sensitive to pressure, but show no external signs of any traumatic or inflammatory changes.

A broad orthopedic shoe, with a Spanish last, was ordered, with the result that an improvement was noted.

CASE V.—S. G., male, aged 27, has been a druggist for the past 18 months.

Personal History.—Five years ago he noticed a pain in the right shin-bone when he walked a long distance. Soon the pain seemed to be in both ankles and feet; his walk changed to a shuffling gait and the insteps of his feet grew more and more painful. He began to work in his brother's drug store 18 months ago, necessitating standing on the feet 12 hours a day. He soon experienced excruciating pains in the fourth toe, quite unlike and independent of former pains. These pains are like dagger stabs. He does not remove his shoes.

Examination was negative, except for knock-knee and a gait typical of everted feet. There is marked flat-foot on both sides. Feet are broad and flattened. Astragalus head and navicular bone are prominent and painful. The ball of the foot is broad and flat. The fourth metatarsal head is exceedingly tender to pressure. There is subluxation in the joint. Pressure from side to side causes paroxysms of excruciating pain in the fourth toe. Beneath the fourth metatarsal head is a painful callus. Plaster impression shows the reentrant angle obliterated, and that the callus under the fourth toe is the lowest point of the foot. I ordered Whitman insoles with a depression in the anterior arch to avoid pressure upon callus. Result: Cured of all pains.

CASE VI.—Dr. M., aged 24.

Personal History.—The patient had a severe injury to the left foot 4 years ago, just before entering his medical college. At the end of the first year in college he was seized with severe burning, cramp-like pains which started in the third toe, and which would extend up along the dorsum of the left foot. He had to take off his shoe in the class-room, he would stamp on the toe with the heel of the right foot, or he would kneel down until the toes were overflexed and the pain would leave with a slight crackling sensation. The agony was so severe that he wanted to have the toe amputated. He finally resorted to broad, thick-soled shoes, made with a flat last (the opposite of the ordinary rocker-soled last) and the pain disappeared. Of late he has worn a pair of ordinary narrow shoes, and the pain has come back, but with diminished severity.

Fig. 7, Case X.—Showing subluxation of second and third toes. Lines retouched on negative.

large and broad. She wears a No. 8-D shoe. No flat-foot. The forward part of the foot, known as the ball, is very flat and spreading. Under each fourth metatarsal head is a painful spot, and the metatarsophalangeal joint is painful to pressure. This joint is not thickened or enlarged on either foot, but is loosely held by the ligaments, and can be partially subluxated, when pressure from side to side sets up the intense pain. röntgen ray examination (Fig. 1) shows absolutely no pathologic changes in the afflicted joints. A plaster cast when the patient is standing shows the sole of the foot to be slightly convex instead of concave, as in normal.

Whitman's plates gave relief, after considerable trouble was taken to get the anterior arch of the plate correct.

CASE II.—J. M., aged 36, is a saleswoman.

Family History.—Distinctly neurotic.

Personal History.—The patient has been "nervous" since childhood, does not remember a trauma to the feet. When 18 she experienced a severe pain in the feet so that she "had to sit on them hard" to stop them from aching. She suffered for 3 years, after which she was well for 7 years. Then she undertook to work in a book store, and walked 3 to 4 miles a day for her health. Three years ago she worked especially hard at her occupation during Christmas season, standing 14 hours a day. This brought on nerve exhaustion and an attack of hysteria. At the same time she complained of an intense burning pain boring right down through the root of the third toe. She does

Examination was negative, except for the condition of the feet. The feet, especially the left, are large, broad and flat. The metatarsal heads are held together very loosely in the anterior arch. The arch is quite lax, and sinks flat to the floor when he stands; in this position pressure from side to side brings back the typical pains. A plaster cast shows the reentrant angle obliterated. I ordered thick-soled orthopedic shoes, which cured all pain.

CASE VII.—Mrs. H. W., aged 34.

Personal History.—Six years ago the patient suddenly experienced terrible cramp-like pains in the fourth toe of the right foot. She was compelled to take off her shoes while walking, shopping, or riding when the pain seized her. She would seize the toe and endeavor to rub and pinch the pain away.

Examination was negative, except for the feet, which show marked signs of having been pinched by narrow shoes. The foot is large and broad; she wears 6-C or 5-E shoe. Careful examination and röntgen ray photograph show no trace of local disease about the fourth metatarsal phalangeal joint, which is, however, painful to pressure. The anterior arch of the foot and reentrant angle of Goldthwaite seem to be normal. The patient obtained in Philadelphia a pair of large, broad-toed shoes with Spanish last, which she wears with toed stockings, with the result that there has been a total absence of all pain.

CASE VIII.—F. B., male, aged 38; letter carrier.

Personal History.—The patient has suffered from rheumatism (?) of both feet at various times; however, he cannot give a coherent history of what could be judged to be real attacks of articular rheumatism. He has never had a severe trauma to the feet. He has been a letter carrier for the past 5 years. Since 3 years ago he has been subject to frequent and severe paroxysms of pain, starting in the ball of the foot, usually under the fourth toe, and shooting upward along the dorsum of the foot. He also experiences pain in the heel, which extends upward along the tendo-achillis to the calf of the leg. Frequently the pain is so severe that he grabs his feet and pulls off his shoes, but for the most part he can control himself. He rarely experiences more than a mild transient pain while walking, but after he sits down to rest he is sure to have one or more severe paroxysms. The pain usually ends with a snapping sensation in the fourth toe.

Examination was negative, except for a large clumsy foot with a slight amount of flat-foot. Anterior transverse arch is only slightly depressed. The fourth metatarsal phalangeal joint on either foot is very sensitive, not thickened or inflamed, but is slightly subluxated, and manipulation of the joint sets up characteristic paroxysms. Pinching the foot from side to side causes same pain.

Treatment was refused.

CASE IX.—Mrs. J. K., aged 40.

Family History.—Negative.

Personal History.—The patient has never had a severe illness nor trauma. She has had a painful fourth toe on the right foot as far back as she can remember. The pain is so intense that she pulls off her shoe no matter where she is, grabs her foot, and begins to rub it. Paroxysms only come on when she wears her shoes. The pain is of a burning stabbing nature.

Examination.—Patient is of a distinctly neurotic temperament, refuses to take off her shoes to let me examine her feet. Pinching the ball of the foot or pressure over the fourth toe of the right foot causes a characteristic paroxysm of pain.

Broad-toed shoes with a Spanish last were ordered, and a great improvement resulted.

CASE X.—Mrs. K., a nurse, aged 35.

Family History.—Negative.

Personal History.—The patient had a severe accident to the feet about 8 years ago. For the past 6 years she has suffered fearful pains, beginning at the sole and radiating upward upon the dorsum and to the ankles. When the paroxysms seize her, she stops, sits down on the floor, pulls off her shoes, and rubs her feet with a liniment, the chief ingredient of which is oil of mustard.

Examination.—She is a large plethoric woman. The feet show marked signs of having been abused by tight shoes. On the soles just under the head of the second metatarsal bone is a large painful callus (Fig. 6). There is slight flat-foot; the foot across the ball of the toes is cyanotic, perspiring, and is very broad, and flattened to a marked degree. The anterior transverse arch is so broken down that the heads of the second and third metatarsal bones are lower than the head of the great toe. When the patient stands, the head of the second metatarsal bone bears the weight of the body upon the floor (see foot-print, Fig. 5). A röntgen ray examination shows that the second and third toes are overextended and subluxated (Fig. 7). The examination was otherwise negative.

Treatment was refused.

CASE XI.—Mrs. R. J., aged 32.

Personal History.—Six years ago the patient was dragged by a runaway horse, her foot having caught in the stirrup. Since then she has been troubled with pain in the right foot, beginning in the fourth toe. The pain is a burning, stinging, boring sensation, which causes her to remove her shoes at times. She can ease the pain by over-extending the toes or by pinching the toe with a hard object.

Examination was negative, except for the feet. The right metatarsal arch is very loosely held together, but does not show

marked flattening. Reentrant angle is not obliterated. When the toe is extended, pressure across the ball of the toes causes intense pain—characteristic spasm. Pressure from below arching the ball of the foot upward feels grateful.

Shoes with Spanish last were ordered, and a great improvement resulted.

ABSCESS OF THE LIVER, CAUSED BY DISTOMUM SINENSE OF THE INTRAHEPATIC BILE DUCTS.

BY

THOS. L. RHOADS, M.D.,

Medical Department, United States Army.

The patient, a sergeant of the Marine Corps, was operated upon at the Naval Hospital, Washington, D. C., in October, 1898; he recovered, was returned to duty, and remains well. The infrequency of the affection in this country makes it of sufficient interest to report the case, which is done by permission of the Surgeon-General of the Navy.

Sergeant G., aged 46, a native of Germany, has had 25 years' continuous service in the U. S. Navy. Was in excellent health until 8 years prior to operation.

The first discomfort which he experienced, and which was the forerunner of his more serious trouble, occurred while on duty on the Asiatic station in 1892. He had looseness of the bowels, and attacks of sharp pain in the epigastrium, of obscure origin, occurring at any and all hours of the day, and covering a period of several weeks. The pain did not incapacitate him for duty, however, and his name was not entered upon the sick report.

In July, 1896, while on duty at Marine Headquarters, Washington, D. C., he was suddenly taken ill with severe epigastric and hypochondriac pains, which lasted several hours. Repeated attacks at intervals of 3 or 4 days, and lasting several weeks, caused great prostration. He described these attacks of pain as though a heavy weight rested under the margin of the ribs on the right side and continued to grow larger. There was anorexia, but no nausea during the attacks. He was slightly jaundiced; his body was covered with a cold sweat, and he was very weak. Morphine was administered, which relieved, but did not control the attacks, and he was invalided in the Naval Hospital, Washington, D. C., for 6 days. Purgation relieved the pain, and at the end of a week he was discharged to duty and remained well for 2 years.

On May 17, 1898, while on picket duty on the blockading

squadron, on the U. S. S. Bancroft off the coast of Cuba, he became overheated in preparing the ship for action at midnight. Returning to his bunk an hour later, he awoke at 3 a. m. with sharp pain over the hepatic area, and a feeling of suffocation. Sinapisms relieved him, and he remained on duty, although he had intense pain every day. He also had a slight cough; bowels were regular. On the night of the twenty-seventh under the same circumstances while preparing the ship for action—all the lights being covered—he ran against a steam capstan, striking his right side over the hepatic region. He was placed on the sick list suffering with great pain, and a temperature of 102° F. He remained on the sick list until June 7, the pain continuing, and was then transferred to the hospital at Key West. Improvement followed under the influence of rest and the administration of salines, although the pain did not entirely leave him. He remained a bed patient until July 6, and was transferred on sick list successively to the U. S. S. Lancaster, U. S. S. Newport, Naval Hospital, Brooklyn, and finally to the Naval Hospital, Washington, D. C., for treatment, at which last station he was admitted on July 31, with a provisional diagnosis of cholelithiasis. His tongue was coated and bowels somewhat constipated, he had slight jaundice, and complained of dull pain in the right hypochondriac region, no tenderness being elicited by palpation over the region of the gallbladder. There were no signs of pleurisy. Calomel in divided doses relieved him greatly, and after keeping him

efforts were made at different depths and in different directions. His condition remained about the same for several weeks, never being quite free from pain, and his temperature ranged from normal to 1 degree and a fraction above, with moderately quickened pulse. He developed in addition evening sweats, without rigors. The line of liver dullness gradually extended upward to the right nipple, shading off to a lower level posteriorly. The lower thoracic measurement was increased 3 cm. on the right side.

Operation was decided upon, after consulting with Medical Director Bright, and was performed with the assistance of Surgeons Grunwell and Benton, United States Navy.

By a curved skin incision in the midaxillary line, a flap of soft structures was turned up, exposing the ninth rib, which was resected, a section 3 inches in length being removed. A semilunar flap of pleura and diaphragm was made, the opening walled off with gauze and a 4 cm. incision made directly into the liver substance. A closed clamp was plunged through this incision to a depth of 5 cm., opened and withdrawn and 120 cc. of thick yellow pus escaped.

On exploring the cavity with the finger, it was found to be divided into several smaller compartments by trabeculae, the cavity extending upward toward the diaphragm, and inward toward the median line posteriorly. These trabeculae were broken down with the finger. The wall of the cavity was slightly indurated, but did not have the solid consistence of fibrous tissue usually met in hepatic abscess. The cavity was irrigated with several liters of hot salt solution, and sponged dry with strips of gauze, care being taken not to disturb the adhesions which existed at points between the parietal and visceral reflection of peritoneum beneath the diaphragm. A large rubber tube was anchored in the posterior angle of the incision, alongside of which gauze strips were packed loosely into the cavity, and the incisions closed by layer sutures, save the opening for drainage.

There was some shock, but on the whole the patient reacted well from the operation. Free drainage necessitated frequent change of dressings for several days following the operation. The primary gauze strips were removed on the third day and the wound cavity irrigated with a sterile solution, considerable pus, shreds of necrosed tissue, and blood-clots being washed away. Tubular drainage was discontinued on the sixth day and gauze alone substituted. The skin sutures were removed at the same time, firm union having taken place. The cavity on ex-

amination at this time was found to have closed in to the size of a walnut, with smooth walls. Three concretions were felt in the cavity, and on being removed with forceps proved to be cholesterin and carbonate of lime calculi. Each was approximately the size of a hazel nut, with markedly eroded surfaces. Further digital and instrumental search revealed no additional concretions. On the following day—the seventh after operation—on irrigating the cavity, 3 parasites, brownish-white in color, 16 minims in length, oblong, somewhat flattened and somewhat pointed toward the anterior end—which was cup-shaped—were washed away in the discharge. On examination these parasites proved to be *distomum sinense*. On successive days ten more of these parasites were discharged, after which the wound healed without event, and the patient was discharged to duty.

The feature of the case is the cause of the hepatic suppuration. The various stages in the process leading up to the destruction of liver tissue undoubtedly found their beginning in a parasitic invasion in 1892—(anteceding the operation 6 years)—the time when the patient served with the Asiatic fleet, and where shore leave in Chinese and Japanese ports, the wellknown endemic areas of *distomum* disease, offered opportunities for the ingestion of unclean food and the indiscriminate use of nonsterile water. The ingestion of the cercariae and their development within the bile ducts, first found expression in pain in the epigastric and right hypochondriac regions, with looseness of the bowels several months after exposure, and similar attacks in succeeding years, aggravated in character, associated with biliary colic and

under observation 2 days, he was discharged to duty without pain or rise of temperature.

On August 25, while on duty at Marine Headquarters, Washington, D. C., he again suffered from pain in the epigastrium and hepatic region. This pain now became radiating and continued so until September 18, when it concentrated in one place above the rib margin, to the right of the median line. There was moderate fever, and neither pain nor temperature responded to coaltar products. September 19 he was readmitted to the Naval Hospital, Washington, D. C., with a diagnosis of hepatitis. He walked with a retarded gait, complained of loss of appetite, and had a slight cough but little expectoration. His tongue was coated, he suffered pain in the region of the liver on deep inspiration and on movement, and his temperature on several preceding days ranged from 99° F. to 101° F.

The liver dullness was increased 5 cm. upward, with friction sounds over the upper part of the hepatic area, the point of the greatest tenderness over this area being 10 cm. above the right costal border, in the anterior axillary line. The abdominal muscles were not rigid, and the liver margin could be readily palpated by the hand. Pressing in the abdominal wall at the margin of the ribs on the right side, and continuing this pressure upward on the under surface of the liver, great pain was elicited at the same point—10 cm. above the right costal border—that was demonstrated by percussion over the thoracic wall. On auscultation air could be heard entering the vesicles over the entire right chest. There had been no chills. He had lost weight during the several weeks prior to admission, and had been feeling badly during this time. He lay in bed with his right leg drawn up and his thigh flexed on the abdomen. His bowels were regular, light brown in color; no nausea or vomiting. Catharsis was secured by calomel and salines, and an effort made to relieve pain by sinapisms locally, without marked effect. Olive oil was administered daily during the following 2 weeks, and while his symptoms decreased in severity, he still complained of some pain with a moderate temperature—100° F.—at the end of this time.

On October 7, an aspirating needle of medium size was plunged into the liver substance at the point of greatest tenderness, between the seventh and eighth ribs, in the anterior axillary line. No pus was discovered, although a number of

jaundice, represent the activity of the mature trematode in the bile ducts in the liver, or its passage into the intestinal canal. Not being suspected, no search was made for the distomum or its ova in the stools.

The cercaria after its ingestion finds its habitat in the bile ducts, where it attains maturity, and the distomum becomes the causal factor of serious hepatic disease. The biliary canals, particularly the intrahepatic ducts, become dilated and thickened, expanding into cavities and diverticula at places, in which sacculated areas numbers of the parasites exist. When the distomas do not escape into the intestine, stenosis of the affected bile ducts takes place, accompanied by inflammatory action within the ducts—catarrhal at first, later suppurative—necrosis results, and the ulceration is followed by abscess, a purely pyogenic infection of the staphylococcus and streptococcus type. In conjunction with the pus formation, there is marked enlargement of the liver, due both to local inflammatory action and to interference with the portal circulation. This represents the pathologic history of the case cited.

The formation of calculi within the intrahepatic ducts was a secondary phenomenon. The distomas in the bile ducts caused a primary catarrhal inflammation and stenosis of these ducts with damming up of bile above the site of occlusion. The excessive secretion of mucus resulting from the inflammatory action decomposed the bile above the site of stenosis, particularly the salts of the biliary acids. To the nuclei were successively deposited the carbonate of lime and cholesterin, until the concretions attained the size found in the abscess cavity. This case, of such cause, is the only one I have met among 21 operations for liver abscess, but the condition is sufficiently important to bear in mind in dealing with hepatic suppuration.

SOME OBSERVATIONS ON THE OCCURRENCE OF NEPHRITIS IN INFANCY.*

BY

CHARLES C. BIEDERT, M.D.,

of Philadelphia.

Until within a comparatively recent period very few observations have been made upon the frequent occurrence of nephritis in infancy, and in this country we are largely indebted to Holt, Jacobi, and Morse, for what work has been done along this line.

Goulkewitch¹ has carefully examined the kidneys of 220 infants at autopsy, from 2 to 9 months of age, and has found evidences of nephritis in 23 cases. The primary disease in the 23 cases was pneumonia, 11; tuberculosis, 6; enteritis, 6.

Morse,² in a paper read before the Philadelphia Pediatric Society, March 11, 1902, has called attention to the subject, and has examined the urine systematically in every infant under his care within the last 2 years, with results that have convinced him that the examination of the urine in infancy should never be neglected; and should be done as a routine measure. He also reports a number of cases both occurring primarily and secondarily.

Jacobi³ says nephritis in the acute, subacute and chronic forms is a very frequent disease in infancy and childhood. There is an occasional hereditary tendency. Even in the newborn it is not infrequent; in these it is either *congestive* from feeble circulation, congenital heart disease, asphyxia, or exposure to low temperature, or it may be *obstructive*, from physiologic rapid decomposition of the blood in the newly born, the formation of hematin—bilirubin, from jaundice, from the production of methemoglobin, by excessive heat, or from the

presence of blood in the uriniferous tubules. It may also be *irritative*, due to uric acid infarctions, by the presence of purpuric, or other hemorrhages, or microbic.

Holt⁴ speaks of nephritis as being quite a frequent affection in infancy and childhood, and quite likely to be overlooked unless the urine is carefully examined with that point in view.

D. J. Milton Miller⁵ reports a case of acute hemorrhagic nephritis complicating influenza in an infant of 13 months, and gives an analysis of 40 cases of influenzal nephritis at all ages. The youngest of his patients was an infant of 5 months and the oldest a man of 65. More than half of the cases were in young adults and children.

Etiology.—It may occur as a primary or as a secondary affection. In this paper we are dealing more with the secondary variety. Jacobi states "that the diagnosis of nephritis should never be overlooked. Almost no diagnosis is complete without an examination of the urine. The examination for albumin should never be omitted in a doubtful case, or in any of the infectious diseases of childhood. The absence of dropsy or *œdema* proves nothing at all, particularly in the very young infant, in whom chronic nephritis without dropsy is a frequent occurrence after pleurisy, pneumonia, etc. Indeed, the most dangerous cases and complicated with uremia, are those in which no dropsical symptoms are apparent. Nephritis as a secondary affection is quite likely to be overlooked until it is too late. When the excessive frequency of this disease is recognized, fatal results will become less frequent and prevention will be appreciated at its full value." The enumeration of the causes of nephritis will always be incomplete, but the list of those conditions and diseases leading to it comprehends the principal ailments of infancy and childhood. First of all there are the acute infectious diseases—scarlatina, diphtheria, measles, rubella, varicella, vaccinia, even malaria, typhoid, cerebrospinal fevers, tonsillitis, parotitis, and pyemia. No bacilli are required to cause toxic nephritis; their toxins do as well. Stasis dependent upon pulmonary and cardiac diseases may act as a cause. In my experience whoopingcough and bronchopneumonia are quite potent causes. Probably all cases have an infectious origin.

The primary form of the disease is very rare in infants. Holt, in 1887, reported 5 cases, and collected 14 other cases from the literature apparently primary. He says: "These cases are not common, and the symptoms are so obscure that they are usually overlooked." And since that time and up to 1902 he had seen 5 additional cases. The cases were mostly of the exudative type.

The secondary form of the disease usually develops at the height of the febrile process, and its severity is generally proportionate to the intensity of the infection. The general symptoms of nephritis are often not marked and dropsy is rare, so that unless the urine is examined the condition is overlooked.⁶

The Urine in Infancy.—The specific gravity is low in infancy, 1,003 to 1,008 the first 4 or 5 days, and rarely above 1,010 the first 6 months, and from 1,006 to 1,012 up to the first 2 years. The reaction is usually faintly acid, the color light and frequently it is cloudy, due to the presence of epithelial cells. The amount of urea is proportionately large, as is also the amount of uric acid. This amount steadily decreases during infancy, but is large throughout childhood. During the first few days of life, albumin is of little significance, but after the first week its occurrence is usually of the same significance as in later life. The same applies to hyaline casts.

Goulkewitch, in his series of autopsies, found that nephritis was more common following pneumonia than in any other disease, and in this respect his observation coincides with my own, as all of my cases occurred following this disease, the pneumonia in 2 cases being a sequel of whoopingcough, and in one a sequel of influenza, in another of acute gastroenteritis. The following

*Read before the Northern Medical Association, Philadelphia, October 9, 1903.

cases are examples of this condition following whooping-cough.

CASE I.—F. H., aged 5 months, was first taken sick July 1, 1903. He had been bottle fed since birth, and had been taking a modified milk mixture of fat 2.5%, proteids 1%, sugar 5%. At this time his temperature was 103°, pulse 125. He had vomited once or twice after taking the bottle, but vomiting had not been excessive; bowels were quite loose—10 or 12 napkins were soiled daily. The excreta were green and foul smelling, and contained mucus. After 3 or 4 days' treatment he had recovered to a great degree. He had at this time a slight cough, but no signs in the chest, and we suspected that he was contracting whooping-cough, as he had been exposed to the contagion. This attack of enteritis was traced to milk infection from allowing the milk to remain on the front doorstep for 2 hours each morning before making the mixture, the weather being warm. On July 13 he was again taken with a high fever, 104°, cough, and diarrhea, and seemed quite ill. On the following day he had two slight convulsions, temperature was 104°, pulse very rapid, bowels loose and greenish. He coughed considerably, and his mother states that on one or two occasions he whooped, cough was spasmodic, and followed by vomiting (a sister has pertussis). He continued in much the same condition until July 20, when the temperature was 104°, pulse 140, respirations 80. Cough was hard with expiratory grunt, some retraction of ribs on breathing. The child seemed quite anemic, and seemed to have pain when he coughed, as he immediately cried after each effort; there was some impairment of resonance at the left apex and base posteriorly—no rales.

On July 22 temperature is 104.4°, respirations 80. He cries after each effort at coughing; physical signs of bronchopneumonia are present. There is noticed for the first time distinct swelling and puffiness of both feet. The anemia is very marked.

On July 23 swelling of the feet has extended to the legs; does not pit on pressure. Temperature 104°, cough hard and dry, scattered areas of bronchopneumonia over both lungs.

On July 24 a specimen of urine was obtained. Specific gravity 1.006, reaction was acid, color clear pale amber; there is a decided trace of albumin (heat and acid test), no sugar, hyaline and light granular casts quite numerous (eight or ten in each field), low power, urine diminished in quantity. His condition remained unchanged, and on July 27 temperature was 103°, pulse 160, respirations 60. Edema and pallor were still present, urine still showed many hyaline casts and numerous pus cells and bacteria; skin hot and dry, physical signs of pneumonia still present.

On July 28 temperature was 104°, pulse 160, respirations 68. He has been sweating slightly and urine still shows albumin, hyaline, and granular casts and pus cells. He passes very little urine, anemia increased, and the general condition steadily grew worse, until death occurred, July 31, after several very hard convulsions, which were probably uremic. No autopsy was allowed.

In the foregoing case, which was clearly one of pertussis complicated with bronchopneumonia and nephritis, I believe that the nephritis operated largely in the production of the fatal termination. Holt, in an analysis of 426 cases of bronchopneumonia, occurring in children below the age of 3, states that in only 3 of his cases was there nephritis, and in all of them it was of the acute exudative variety, but that in only 1 case was it severe enough to affect the prognosis.

CASE II.—James L., aged 4 months, was first seen January 19, 1903, in the second week of the convulsive stage of whooping-cough, with a temperature of 103.2°; pulse, 130; respirations, 50. He was sick for about 12 days, with constant crying and fretting, and hard spasmodic cough followed by vomiting. The lungs showed rales and suggestion of bronchial breathing posteriorly under the angle of the right scapula. He continued in this condition with symptoms of bronchopneumonia for 4 days with marked nervous symptoms, twitching of muscles, etc. Mother noted that he passed very little urine. Specimen examined at this time showed reaction acid; albumin, faint traces, full of amorphous urates, a few uric acid crystals, no casts.

He now apparently improved. Temperature became normal and subnormal for 10 or 12 days, when he took fresh cold and had a relapse. Temperature, 103.2°, and symptoms of bronchopneumonia returned. Examination of urine February 22, about 4 weeks after he was first taken sick, shows reaction acid; color, cloudy, pale amber; heavy white sediment, albumin present, marked trace, and numerous hyaline and granular casts, pus cells in abundance, and amorphous urates and uric acid. There is no edema of any part of the body, baby seems quite anemic, physical signs and general conditions are indicative of severe bronchopneumonia.

March 2, urine is cloudy amber, contains sediment of urates, hyaline and granular casts, uric acid, and numerous pus cells. He continued to grow worse. The pneumonic process spreading throughout both lungs, and he died March 12, after an illness extending over 53 days.

This case represents the protracted or persistent form of bronchopneumonia, and is quite common following pertussis; and quite frequently runs on with exacerbations, and remissions for 8 or 10 weeks. It usually terminates fatally. In this case there was at no time any edema, and the only symptoms which would lead to the diagnosis of nephritis as a complication was the diminished amount of urine and the pallor, and these 2 symptoms suggested the examination of the urine. In this case the nephritis was not severe enough to affect materially the prognosis. Death was evidently due to asthenia and toxemia due to the protracted bronchopneumonia. Two other older children in the family had whooping-cough at the same time.

Miller in an analysis of 40 cases of nephritis following influenza only found 1 case beside his own in infancy. He therefore, concluded that nephritis as a complication of influenza in infancy is very uncommon; this I believe to be due in part to the fact that the urine in infancy is frequently overlooked, and that if more attention was paid to the examination of the urine the condition would be very much more frequently found. The following case is an example of this.

CASE III.—Ruth D., aged 7 months, bottle fed (modified milk formula), was taken sick 2 or 3 days before I first saw her on February 10, 1903. Mother stated that several members of the family had had bad colds with sneezing and running of nose, and general catarrhal symptoms, and baby was first taken sick with the same general symptoms. When I first saw her, her temperature was 104°, pulse 150, and she had marked catarrhal symptoms indicative of influenza. Chest full of moist rales no consolidation was noted.

Four days later, February 14, temperature was 104°, pulse 150, respirations 55, chest full of sibilant rales; some bronchial breathing in areas, cough very troublesome.

She continued in pretty much the same condition until February 21, when it was first noted that baby was extremely pale, but there were no signs of edema. The secretion of urine was very little for a few days past, and mother noted that she did not wet more than 2 or 3 napkins in 24 hours, and this a very little at a time. I was unable to obtain a specimen of urine for examination. Cough is very troublesome and signs of bronchopneumonia still present. On February 24, she had 2 or 3 convulsions, the movements mainly involving the muscles of the face, very little movement of the arms and legs. On February 28, pallor was very marked, she passed very little urine and there was some slight swelling of the dorsum of the feet. A specimen of urine was obtained. It showed a marked trace of albumin, amorphous urates, and kidney epithelium. No distinct casts were found. She continued in this condition, one day slightly better and another worse, the edema of the feet gradually increasing in spite of treatment; the pallor was also very marked, and the amount of urine secreted very low. She died suddenly on March 4, after an illness lasting 25 days.

Autopsy showed extensive involvement of both lungs posteriorly. There were scattered areas of consolidation over both lungs, more marked on the right side, lung tissue was friable, and on section exuded pus and blood. The anterior portion of both lungs was free. There were also recent pleural adhesions on both sides which were broken up with some difficulty. Spleen was congested and soft, the liver was large and congested. Both kidneys were congested and red. Capsules stripped easily. The surface of the kidneys was covered with congested bloodvessels giving the kidneys a mottled appearance. On section they exuded considerable blood, and the cortex was narrowed and pyramids diminished in size.

More attention has been paid to the occurrence of nephritis following gastroenteric diseases than of any other. Morse,¹ in a series of 70 cases, found evidence of renal involvement in 15%.

Holt says acute degeneration of the kidney is found to some degree in every case which is severe enough to cause death, and in a few there is acute diffuse nephritis.

The following case began as an acute gastroenteric infection, and bronchopneumonia and nephritis developed as a secondary condition.

CASE IV.—Henry J., aged 4 months, was bottle fed for a month, then on condensed milk, and later on the modified milk formula. He was first taken sick August 22, 1902, with vomiting, purging and high fever, movements were watery, foul smelling and contained mucus. He vomited all food and grew extremely weak and emaciated. He had 10 or 12 movements daily. Under treatment bowels improved and the child grew better for a few days. On September 1, he was again taken with high fever and cough, although he had not been

well since his first attack of diarrhea. Temperature was now 103.2°. He coughed almost constantly and was very weak. He had the physical signs of bronchopneumonia, was very much emaciated, bowels loose (8 movements daily and containing slime). He is very stupid and drowsy; mother states that baby was swollen all over the body; he is very anemic. Examination of the urine showed a marked trace of albumin, it was full of pus cells and many granular casts. Urine diminished in quantity, child grew rapidly worse and died September 3, after having had 1 or 2 convulsions. No autopsy was allowed.

Cotton⁸ in discussing the symptomatology of summer diarrhea in children states that while the frequent occurrence of albuminuria in patients with summer diarrheas, has led observers to regard the condition as nephritis, he believes that functional cardiovascular conditions with the anemia rapidly induced by the colliquative discharges, to be a rational explanation for many of the cerebral phenomena, and the edema of dependent parts.

I do not believe the foregoing cases can be explained on these grounds, as all except perhaps Case II, had all of the classic symptoms of acute parenchymatous nephritis, namely, anemia, edema, marked nervous phenomena and convulsions, and the urine in all cases showed evidences of the desquamation of kidney substance; in all cases there were decided traces of albumin and many hyaline and granular casts. In some instances kidney cells were found upon microscopic examination. I was only fortunate enough to obtain an autopsy in 1 case, and in this the pathologic findings showed marked disease of the kidneys.

What the further history of these patients would have been in regard to the condition of the kidneys had they recovered I am not prepared to say, but I believe that owing to the wellknown recuperative powers of the tissues of children no permanent changes would have occurred; but I am firmly convinced that the kidney complication played an important part in the fatal issue of these cases.

In conclusion I wish to emphasize the following points:

1. The importance of examining the urine in all acute diseases of infancy, and especially in the bronchopneumonias.
2. The importance of marked anemia as the most pronounced symptom of kidney involvement.
3. Edema may or may not be present, but when it is present it constitutes a valuable sign, but there may be grave kidney involvement without edema.
4. There is almost always a diminished secretion of urine, the mother almost always noting that the baby wets fewer napkins.
5. There are almost always grave nervous phenomena and convulsions, which in some cases are probably uremic.

Though all of the cases reported had a fatal issue, still I have reported them with the view of calling attention to this complication, and, perhaps, stimulating further research along this line.

To Combat the Sweatshop Evil.—The United Garment Workers, the Philadelphia Branch of the Consumers' League, and the Pennsylvania Association of Women Workers are preparing a circular which sets forth some of the evils of sweatshop and child labor in as simple and graphic terms as possible. This circular is to be first taken to the heads of the large department stores and manufacturers, and the names of those who are willing to allow their firm names to be used as carrying goods bearing the Union and Consumers' League labels are to be published in a few days.

MYXEDEMA COMPLICATED WITH DIABETES MELLITUS OCCURRING IN TWO CHILDREN. EFFECT OF THYROID EXTRACT UPON BOTH DISEASES. REMARKS ON THE PATHOGENESIS OF DIABETES.¹

BY

ALFRED GORDON, M.D.,
of Philadelphia.

Instructor in Nervous Diseases, Jefferson Medical College; Assistant Visiting Neurologist to Philadelphia Hospital; Neurologist to Douglas Memorial Hospital.

Diabetes mellitus in early childhood is, comparatively speaking, a rare condition. There are on record numerous cases attended with the excretion in the urine of minute amounts of sugar, but they differ clinically from the true diabetic types. They are designated as cases of simple glycosuria. The cardinal symptoms of diabetes mellitus—namely, excessive thirst and hunger, polyuria and considerable excretion of sugar, independently of a carbohydrate diet—present a distinct pathologic condition which is very unusual in early life. Romberg, according to Kleen, observed among 5,900 infant patients but a single case of diabetes.

Myxedema, on the contrary, is relatively of frequent occurrence in childhood; at least, the percentage of myxedematous children is much higher than that of myxedematous adults. Not infrequently myxedema is accompanied by a slight glycosuria. In the asylums I have often seen cases of cretinism complicated with a slight glycosuria or albuminuria, but I never had the opportunity to observe nor am I familiar with a case of myxedema complicated with a true diabetes. The relationship between myxedema and a faulty function of the thyroid gland is well known, but the role of the latter in the creation of the pathologic condition known as diabetes mellitus is comparatively unknown. In *Pfäuger's Archiv*, 1899, Vol. lxxvii, p. 104, we find that Blum observed glycosuria in a dog which he fed on thyroid for several days. Ewald, Strauss, and others also observed the same phenomenon. On the other hand, diabetes has been seen in diseases of the thyroid gland. A relationship between the thyroid function and diabetes therefore exists, and any new data concerning the elucidation of this subject are certainly very desirable, as the latter is far from being solved.

The cases I am about to report are in my opinion, of extreme interest. They will serve to connect the clinical facts and the experimental data of the subject. They corroborate what others have observed only on animals in the laboratories. To a certain extent they will contribute to a better and broader conception of the mysterious disease called diabetes. Finally, practical therapeutics may benefit from the results obtained from thyroid medication. The cases are as follow:

CASE I.—H. B., a male, aged 3, was first seen by me in January, 1903. His father, who was under my care for pronounced neurasthenic symptoms, often complained to me of his child being unwell for the past 6 months. In spite of the best possible care advised by the family physician, the child was gradually failing in health. Questioned closely, my patient gave me the most prominent symptoms observed in the child, namely, ravenous appetite and thirst, frequent and abundant micturition, gradually increasing mental dullness and apathy, extreme pallor of the skin. The child was brought to me for an opinion. At first glance, perhaps, nothing abnormal could be detected, except the waxy, yellowish skin of the face. A closer study elicited the following points, although they were not markedly developed: Puffiness of the eyelids; the skin of the face slightly edematous, but without pitting and extremely dry. The father of the child positively states that his face, lips, hands, feet, and abdominal walls are distinctly larger than they were 6 months ago, and that the whole body became puffy and was gradually getting larger. The most striking symptoms, however, pertained to the mental state of the patient. He could hardly answer and understand the questions asked of him; and when he would answer, he would do it in a slow and deliberate manner. His eyelids would droop often during the conversation, which evidently fatigued him considerably. The indiffer-

¹ Read before the Philadelphia County Medical Society, December 9, 1903.

ence of the child to his surroundings was distinctly noticeable, while he used to be playful and intelligent. A visceral examination showed slowness of respiration and of heart-beats. Pulse was 60. The teeth were apparently normal; the hair according to the father, suffered in its nutrition. The mucous membrane of the nose was very dry. During the half-hour the child spent with me, he drank 3 glasses of water and asked for more. A specimen of urine was taken on the spot and gave immediately the characteristic Fehling reaction for sugar. Before I saw the patient, his father's statement in regard to the excessive thirst and appetite made me think of infantile diabetes, and the mental symptoms related to me, were, in my mind, due to the same disease, as diabetes is known to produce nervous and mental derangements. However, when the patient appeared before me, and after a moment's observation, I could not hesitate to pronounce it a case of myxedema, although the symptoms, as I said before, were not pronounced.

Before treatment was instituted, I decided upon a more careful and repeated urinalysis. Specimens of urine taken morning and evening were examined chemically and microscopically, and the following was the result: The amount could not be determined, but from the parents I learned that the micturition was very frequent and abundant. Reaction, sharply acid; sp. g., 1.038.5; no albumin; but glucose present. Microscopically no abnormal elements could be found. The presence of sugar was tested repeatedly by Trommer's method, also by Fehling's and Pavy's solutions. The reaction was exceedingly prompt and the quantity was evidently large, although an exact quantitative analysis was not made. It may be of some interest to tell the result of the blood-examination before the treatment was instituted: Hemoglobin, 50%; erythrocytes, 2,750,000; leukocytes, 14,000; differential count shows a normal proportion of the various leukocytes, without eosinophiles.

So soon as the diagnosis of diabetes was established, I made 2 more inspections of the child, and was more and more convinced that it was a case of myxedema complicated with diabetes.

Before I relate the management of the case and the subsequent course of the 2 diseases, I shall give briefly the history of the second patient.

CASE II.—A. B., aged 4½ years, a brother of the first patient, presented the same symptoms, with this difference, however, that the physical symptoms as well as the mental and the quantity of sugar in the urine were still more pronounced. The myxedema was too evident to be overlooked. The mental symptoms consisted in extreme apathy with outbreaks of excitement. He also presented decayed teeth, very little hair, and brittle nails. His malady dated from the age of 2, so that the symptoms had had more time to develop. The diabetic symptoms were identical with those of his brother. Both patients presented an anomaly which I purposely did not mention before—namely, total absence of the thyroid gland; at least, no trace of the organ could be detected upon repeated examinations. Both patients also presented marked symptoms of anemia, but no symptoms pointing to an organic lesion of the nervous system; gait, station, reflexes, and sensations were found to be normal. The family history presents a few interesting points. The grandfather was committed several times for delirium tremens. Alcoholism and sexual excesses were noted in him even before he was married. One grandmother suffered for years from attacks of gout and migraine. The father of the children is a neuropathic individual, suffering from obsessions. The mother is obese and has been treated for diabetes.

The management of both cases presented, in my opinion, some difficulty at the beginning. Cases of myxedema with some glycosuria are not very rare occurrences, but the glycosuria in such cases is transitory in character, and at all events too insignificant to require special attention. Cases of myxedema complicated with a true diabetes mellitus is, indeed, an extremely exceptional affection, at least, to my knowledge, as in the literature of the last 4 years not a single case was reported.

As I have said before, it was somewhat perplexing for therapeutic purposes to determine how these 2 diseases influenced each other, or whether we had to deal with 2 individual affections independent of each other.

It is an established fact that myxedema is always associated with some defect in the function of the thyroid gland. Although this mysterious function is not entirely cleared up, yet it is well known to produce various pathologic conditions. This view is based on a supposed internal secretion of the gland. On the other hand, diabetes, at least a form of it, is also supposed to be the result of an internal secretion of the islands of Langer-

hans of the pancreas. The doctrine of the internal secretions of ductless glands or of glands with ducts is not only captivating, but it is sometimes unavoidable for diagnostic and therapeutic purposes; it simplifies considerably our conception of many morbid conditions. It is true, this mysterious function is not yet a demonstrated physiologic truth in all cases, but the few clinical and experimental data we are now in possession of in regard to some glands, as, for example, the thyroid gland or the suprarenal bodies, make us believe that there are more pathologic conditions dependent upon this curious function than we know.

Basing myself upon these few thoughts, and also upon the clinical observation that the slight glycosuria noticed in some cases of myxedema disappeared with the improvement of the disease itself, I asked myself if the same lack of thyroid internal secretion, which is probably the causative factor of the myxedema in our 2 patients, is at the same time the cause of the diabetes. The subsequent course of both maladies proved it to be highly probable. I administered thyroid extract in the following manner: .016 gm. (½ gr.) to the younger, and .032 gm. (1 gr.) to the older child, to be taken twice a day at the beginning. Hydrotherapy, in the form of spongings, followed by massage, outdoor life, and substantial food were, of course, not ignored. At the end of the first week a slight improvement was noticed. As there were no untoward symptoms from the thyroid extract, the doses were increased to 3 times a day. Both children continued to improve. During the third week thyroid was given 4 times a day. Every following week the remedy was increased in the manner mentioned. It is interesting to note that the improvement began first of all to show itself in the mental state of my little patients; the languor, apathy, and mental dulness gradually disappeared, and only then the general nutrition changed. The thickness, the pallor, and the puffiness of the integuments gradually but slowly improved; the skin and mucous membranes acquired a healthier color. As to the diabetic triad of symptoms, it is very interesting to know that by the end of the first week the extreme thirst and hunger diminished simultaneously with the improvement of the mental condition, and urinalysis showed marked diminution of the quantity of sugar, so far as we could judge from a gross examination. The improvement in this direction was still more marked at the end of the following week.

It is also important to note that the thyroid medication showed its beneficial influence upon the diabetes mellitus far more promptly than upon the myxedema. This latter observation led to the idea of the great relationship between thyroid internal secretion and the still unknown etiologic agent of diabetes. It was more conclusive, in my opinion, than a most carefully carried out experiment. At the end of 6 weeks, the thirst and hunger became normal, the polyuria disappeared, the specific gravity of the urine went down to 1.022, and the glycosuria was reduced to a minimum. The treatment which has been outlined was persevered in for 4 months, at the end of which time the traces of glucose had disappeared. The children became playful, lively, happy, and mentally normal. The myxedematous appearance changed entirely. At that period of treatment I reached a daily dose of .2 gm. (3 gr.) for the first and of .3 gm. (5 gr.) for the second child. The wellknown excitant effect of large doses of thyroid began to show itself at that time; the patients began to manifest a restlessness, partial insomnia, and irritability. The treatment was then discontinued, but hydrotherapy kept up.

After an interval of 3 weeks some symptoms began to return, namely, the mental hebetude and glycosuria. The treatment was resumed in gradually increasing doses, and was again attended by disappearance of the symptoms. This time, however, there was no indication to reach the maximum doses of the thyroid; .065

gm. (1 gr.) per day for one and .13 gm. (2 gr.) for the other child was sufficient to maintain the patients in good physiologic equilibrium. For 2 consecutive months the treatment was continued, with weekly urinalyses. The patients' conditions were as satisfactory as could be desired. A sojourn at the seashore without medication was advised and carried out. The treatment has not been resumed since then, and there has been no recurrence of either of the 2 diseases.

To sum up, we have here 2 cases of myxedema with genuine diabetes mellitus in brothers, who are the offspring of neuropathic parents with degenerative tendencies. Thyroid extract in both patients showed a very favorable influence upon both morbid conditions, and even earlier on the diabetes than on the myxedema.

The cases present several unusual features: (1) The coincidence of myxedema and a genuine diabetes mellitus (not a simple glycosuria); (2) the occurrence of diabetes in early childhood; (3) the occurrence of both diseases in 2 brothers, showing a degenerative hereditary tendency; the latter is corroborated by the interesting family history; (4) the remarkable effect of the thyroid extract upon the diabetes, explaining with a great degree of certainty the role of the thyroid gland in the as yet unknown pathologic metabolism, which is manifested in a group of symptoms called diabetes mellitus.

An analysis of all the facts concerning the origin of diabetes will show to an impartial observer that so far none of the theories advanced suffices to explain all the phenomena of the malady. We can only say that it seems to be highly probable that independently of the digestive function there is a special internal secretion of the pancreas which is at fault. On the other hand, how to explain the fact that diseases of other organs, including the central nervous system and the ductless glands, are sometimes accompanied by the symptom-group of diabetes. Herter, Richards, Blum, and Wakeman have shown the important relationship between glycosuria and the power of adrenalin, and particularly the effect of adrenalin upon the pancreas. In other words, the production of glycosuria consequent to the introduction into the system of adrenalin was due to a special effect of this substance upon the pancreas. The physiology of the ductless glands (thyroid, thymus, spleen, suprarenals, pituitary body, and others) is known to us only in part; much is to be studied yet. The doctrine of internal secretions of these glands, if correct, explains many physiologic phenomena heretofore obscure.

The fact that the pancreas, with its internal secretion, may be influenced by an internal secretion of the adrenals, militates in favor of the view that the pancreatic secretions may be influenced by secretions of other ductless glands. Pineles¹ and others called attention to the fact that changes which occur in one of the ductless glands may lead to alterations of other glands. Diabetes, for example, may appear in the course of Graves' disease or of acromegaly. Changes in the thyroid gland may alter the function of the pancreas, and *vice versa*.

At the last International Medical Congress, at Madrid, Lorand, of Carlsbad, showed that glycosuria and diabetes occur in acromegaly only when the function of the thyroid gland is exaggerated.

That diabetes has been seen in diseases of the thyroid gland is a well-established fact, and the 2 cases reported here serve to corroborate conclusively the fact that deficient function of the thyroid is capable of impairing the general nutrition of the organism by rendering it myxedematous, and at the same time interfere with the carbohydrate metabolism. Whether the thyroid disorder is the direct cause of the diabetes or acts indirectly through the pancreas similar to the effect of the adrenals, as mentioned above, it is difficult to say. The fact nevertheless remains that when the absent or

deficient thyroid was artificially supplied to the suffering organism, the diabetic symptoms disappeared *in toto*. It therefore establishes beyond doubt a certain if not an integral relationship, between the pathologic process known as diabetes and the function of the thyroid. From the practical standpoint this observation may be of great value, as it puts in our hands an excellent medication for an affection which we have the greatest difficulty in combating. There is another point to which I wish to call attention. Diabetes, especially in children, usually presents an unfavorable prognosis. Our cases, on the contrary, presented a very favorable course and were satisfactorily influenced by thyroid treatment.

Is not this circumstance an indication that a diabetes dependent upon a deficient thyroid function is a form far less grave than the form of the disease which is caused directly by destruction of or a pathologic condition of the islands of Langerhans?

SPECIAL ARTICLES

MEDICUS ET MEDICA.

BY

HELEN MACMURCHY, M.D.,
of Toronto, Canada.

The retirement of Mrs. Garrett-Anderson, M.D., from the office of Dean of the London School of Medicine for Women, which she has held during the last 20 years, will recall many memories to the minds of the men and women who were her comrades 20 years ago. Memories not only of 20 years ago, but of 40 years ago, for it was in 1860 that Mrs. Garrett-Anderson (then Miss Elizabeth Garrett) presented herself at Apothecaries' Hall. Well might the little band of survivors of these days of diplomacy and conflict say to us "*Quæque ipse vidi et quorum pars magus fui.*"

It is not to be forgotten that if women have learned this art of healing, men have taught it to them, in the first instance at least. Many medical men did this willingly and cheerfully, some did it *con amore*, with a generous enthusiasm. There are few men, after all, who would not agree with Mr. Grote in saying that whenever a woman has a real love for learning in her youth, and a genuine aspiration after an independent and self-maintaining position, she should at least have as fair a chance as a man of using her talents to the utmost, or who would not say with Mrs. J. S. Mill: "We deny the right of any portion of the species to decide for another portion, or any individual for another individual, what is, and what is not, the 'proper sphere.' The proper sphere for all human beings is the largest and highest to which they are able to attain. What this is cannot be ascertained without complete liberty of choice."

It was in 1844 that Miss Elizabeth Blackwell began her medical studies in the United States. Of English birth, she had lived in America since early youth, and having set her heart on being a doctor, had taught for some years and saved a sum of money for this purpose. She applied to 13 medical colleges for admission, and was refused at all but one—Geneva Medical College, New York State—in which the faculty left the matter to the decision of the students. The students decided that the lady should be admitted, and Dr. Blackwell graduated in 1849. She studied in St. Bartholomew's Hospital, London, returned to practise in New York in 1851, and in 1854, with her sister, Dr. Emily Blackwell, and her friend, Dr. Zakrewska, founded the New York Infirmary for Women and Children.

Dr. Blackwell was a pioneer of pioneers. She suffered much misunderstanding and passed through much obloquy, but she lived to practise the profession she loved for many years, in peace and honor, retiring only recently and returning to her native country.

The oldest woman's medical college in the world is in Philadelphia. Dr. Fussell, a Pennsylvania Quaker physician, seems to have been the first who thought of founding such a college, and there is in existence a private letter in which this idea is traced to the respect and affection he felt for his eldest

¹ Volkmann's Sammlung klin. Vorträge, No. 242.

sister, a woman of remarkable gifts. "Why," said Dr. Fussell, "should not women have the same opportunities in life as men?" Two other physicians among the founders of the college were Dr. Hiram Corson and Dr. Charles Thomas.

In 1850, the Female Medical College of Pennsylvania was incorporated by Act of Assembly, its name being changed in 1867 to the Woman's Medical College of Pennsylvania. In the first graduating class was the gentle and brave Dr. Ann Preston, who was afterward appointed professor of physiology and hygiene, and subsequently dean of the faculty (which positions were held by her until her death in 1872), and of whom it was said "The college was Ann Preston, Ann Preston was the college."

Dr. C. N. Peirce, one of the corporators, said at the college jubilee: "That frail and friendly form, that Quaker poet and prophet, with her quiet spirit, represented a force and influence worth a regiment of men." Seven other ladies graduated in Dr. Preston's class, and now the number of graduates of this college practising over the whole world is over 1,000. "The work of these 50 years has all been done in the modest Quaker way, with no parade, no advertisement, and no debts."

The first woman to go to a foreign land as a medical missionary was a graduate of this college—Dr. Clara Swain (class of 1869), the first hospital for women in Asia was the gift of the Nawab of Rampore, at the request of Dr. Swain, and the first Hindu woman to receive a medical degree was a graduate of this college, Dr. Anandibai Joshee, of Poona (class of 1886). Dr. Clara Marshall, a wellknown Philadelphia physician, is the present dean.

Closely connected with this college, is the Woman's Hospital of Philadelphia, founded in 1861 by Dr. Ann Preston, Dr. Emeline Cleveland, and their friends, in which advanced medical, surgical and obstetric work is done, as well as specialists' work. The patriotism and enterprise of this hospital are well illustrated by the fact that in 1898, Dr. Ella Everett, Chief Resident Physician, obtained the necessary change in the Hospital Charter to allow the admission of men as patients, and the hospital equipped and managed a special hospital train to bring sick soldiers from Camp Meade to Philadelphia, afterward caring for about 100 sick and wounded soldiers in the wards of the hospital. Two other hospitals closely connected with this College are the West Philadelphia Hospital for Women, and the Hospital and Dispensary of the Alumnae of the Woman's Medical College of Pennsylvania.

There were 6 women physicians in Philadelphia as early as 1852, and there are few cities where hospital facilities for women are so good, and where young women entering the profession can turn with as much confidence to older women of experience, skill and kindness, in their professional difficulties.

The New York Infirmary for Women and Children was founded in 1854 and in 1865 a Medical College for Women was opened in connection with it, which did good work until, in 1899, Cornell University opened its medical department in New York City and announced that women would be admitted to it. It was felt by the trustees and friends of the college that "the wider opportunities for medical education now open to women in this city render a separate medical school for women unnecessary," and the New York Medical College for Women was closed, so far as undergraduate work is concerned, but it still maintains its postgraduate course.

As Dr. Emily Blackwell said at the thirty-first (and last) annual commencement of the college "We have held open the door for women until broader gates have swung wide for their admission."

The Northwestern University Woman's Medical College, formerly the Chicago Woman's Medical College, was founded in 1870, chiefly by Dr. Byford and Dr. Mary H. Thompson. The present name of the college was assumed in 1891, when it was made a department of the Northwestern University. The excellent work of this school may be estimated by the fact that 340 of its graduates have filled or are now filling hospital positions. Dr. Marie J. Mergler, a gifted woman and a distinguished surgeon, whose recent death is so deeply regretted, was dean of this college.

Dr. Mary Thompson, who with the assistance of Dr. Byford and others, founded the College and the Chicago Hospital for

Women, had studied at the New England Female Medical College and at the New York Infirmary for Women and Children under Dr. Elizabeth Blackwell and Dr. Emily Blackwell. The hospital is now named in her memory, The Mary Thompson Hospital.

Dr. Byford was in a very special sense the founder of this college. The meeting at which the resolution to found the college was passed was held in his office. Overcoming great obstacles in early youth, he rose to be Professor of Obstetrics in Rush Medical College, Chicago, and President of the American Medical Association at the age of 40. He was one of the founders of the Chicago Medical College, an author of repute, and the President of the Woman's Medical College from 1870 till his death in 1890. "The world needs the woman doctor" this great physician used to say, and his only regret was that so good a cause should need a champion.

The Board of Regents of the Michigan University authorized classes for the medical education of women in 1870, and since that time about 400 women have graduated in medicine from this University. "The course of instruction for women is in all respects equal to that for men. Practical anatomy is pursued by the two sexes in separate rooms, but in the lectures, in the public clinics, in the several laboratories, and the various class exercises, it is found that both sexes may attend with propriety at the same time."

In 1898 the University received a legacy of \$140,000 from Dr. Elizabeth H. Bates, of Port Chester, N. Y. This bequest was made on account of the deep interest Dr. Bates took in the medical education of women, and as a recognition of the efforts of the University to give to her alumnae a medical course equal to that given to her alumni.

The Woman's Medical College of Baltimore was founded in 1882, and has already graduated about 80 students. These graduates have come from 19 States of the Union, and one each from Canada, Corea and Germany.

Early provision was made in Boston for the medical education of women. In 1859 Dr. Marie E. Zakrewska (whose remarkable career in Germany is well known) was appointed professor of obstetrics in the New England Female Medical College, and it was through her influence that the work of the New England Hospital for Women and Children began in 1862. The hospital was incorporated in 1863 with the object of assisting educated women in the study of medicine, and providing competent women physicians. The work of the hospital has greatly increased, and grants from the Legislature as well as private munificence have made it possible to erect the present beautiful hospital. The name of the street on which the hospital is built was changed from Codman avenue to Dimock street, in memory of Dr. Susan Dimock, who was appointed resident physician in charge of the hospital in 1872, at the early age of 25. In 1875 she sailed for Europe on leave of absence for study and recreation and she lost her life on the ill-fated steamer *Schiller*, which went down on the Scilly Rocks. She was deeply mourned by the medical profession and indeed by all the citizens of Boston, and her loss was greatly felt by the institution which she had so faithfully served.

The New England Hospital for Women and Children has been fortunate in its friends. The founder, Dr. Zakrewska, served the hospital for nearly 40 years. "In memory of her devotion to the hospital, and in recognition of her unparalleled services" the first building erected and owned by the corporation was named after her. Her portrait was also presented to the hospital by her pupils. Among other friends of the hospital should be mentioned Dr. Henry I. Bowditch, consulting physician since 1865, who was chiefly instrumental in inducing the Massachusetts Medical Society to admit women to fellowship; Mr. Conant, of Roxbury, who endowed the hospital with over \$50,000; and Colonel Albert A. Pope, who gave the new Pope Dispensary Building in memory of his twin sisters, Dr. Emily Pope and Dr. Augusta Pope (who were among the earliest and most devoted of the doctors of the hospital) and in grateful remembrance of the skilful and loving care of the other members of the hospital staff toward one of his sisters during a long and dangerous illness.

The present chief resident physician at the hospital is Dr. Stella M. Taylor, a graduate of the Woman's Medical College, Toronto, and of Trinity University.

It was the intention of Johns Hopkins, in founding a university and hospital at Baltimore, that a medical school, of which the hospital should be a part, should ultimately be established in connection with the University. The University was opened in 1876, and hospital in 1889, but for the medical school there was required an additional endowment of \$500,000. A gift of \$100,000 was presented to the Trustees in 1890 by a committee of women interested in obtaining medical education for women, and in 1892 Miss Mary E. Garrett presented over \$300,000, thus enabling the Trustees to make up, with other sums on hand, \$500,000, and open the medical school in 1893. The first of these liberal gifts was made upon a condition accepted by the following official document:

The President and Board of Trustees of Johns Hopkins University have received from Mrs. Nancy Morris Davis, chairman of one of the committees formed for the purpose of raising a fund to procure the most advanced medical education for women, the gratifying intelligence that \$100,000 has been raised for the use of their intended medical school, and is at their disposal if they will, by resolution, agree to the terms upon which the money was contributed by its donors.

These terms are that this Board, if it accepts the funds thus raised shall agree, by resolution, that when its medical school shall be opened, women whose training has been equivalent to the preliminary medical course prescribed for men, shall be admitted to such school upon the same terms as may be prescribed for men.

The offer to this University of this particular fund is the free voluntary act of women residing in this State and in other States, made without the suggestion or solicitation of this Board, and we accept it under and subject to the terms which are made part of the gift, with the understanding and declaration, however, that such preliminary training in all its parts shall be obtained in some other institution of learning devoted, in whole or in part, to the education of women, or by private tuition.

The fund so contributed shall be invested and known as "The Women's Medical School Fund," and that fund, and all interest to accrue thereon, and all additions made thereto for the same purpose, shall remain invested for the purpose of increase only until, with its aid as a foundation, a general fund has been accumulated amounting to not less than \$500,000, and sufficient for the establishment and maintenance of a medical school worthy of the reputation of this University, and fully sufficient as a means of complete medical instruction. Then, and not until then, will a medical school be opened by this University; and then, and not until then, will the gift now offered be used by this University; and then, and not until then, will the terms attached thereto be operative.

The utility of a training school for women nurses has been demonstrated by the experience and practice of the Johns Hopkins Hospital, and by the necessities of home life among our people.

This Board is satisfied that in hospital practice among women, in penal institutions in which women are prisoners, in charitable institutions in which women are cared for, and in private life, when women are to be attended, there is a need and a place for learned and capable women physicians; and that it is the business and duty of this Board, when it is supplied with the necessary means for opening its proposed medical school, to make provision for the training and full qualification of such women for the abundant work which awaits them in these wide fields of usefulness.

The Mary Elizabeth Garrett Fund was accepted by the Trustees upon similar terms, and it was also provided that not more than \$50,000 of the original endowment of \$500,000 be expended on a building or buildings; and that in memory of the contributions of the committees of the Women's Medical School Fund, this building, if there be but one, or the chief building, if there be more than one, should be known as the Women's Fund Memorial Building, and that there should be created a committee of six women to whom the women studying in the medical school might apply for advice concerning lodging and other practical matters, and that all questions concerning the personal character of women applying for admission to the school, and all nonacademic questions of discipline affecting the women studying in the medical school should be referred to this committee, and by them be in writing reported for action to the authorities of the University; that the members of this committee should be members for life; that the committee, when once formed, should be self-nominating, its nominations of new members to fill such vacancies as may occur being subject always to the approval of the Board of Trustees of the University.

The Women's Committee of the Medical School for 1902-1903 is: Miss Mary E. Garrett, Miss Mary M. Gwynn, Mrs.

William H. Howell, Mrs. Henry M. Hurd, Mrs. Howard A. Kelly, Miss M. Carey Thomas.

Since the graduation of the first class in the medical department of Johns Hopkins University, some 6 years ago, 5 women have been appointed as resident medical officers in the Johns Hopkins Hospital, and one woman, Dr. Elizabeth Hurdon, a Canadian, and a graduate of Trinity University, and the Woman's Medical College, Toronto, holds a place on the Johns Hopkins Medical Faculty as assistant in gynecology.

There were 3,000 women physicians in the United States in 1889; 4,555 in 1896, and now there are probably 6,000.

The last report of the Hon. W. T. Harris, Commissioner of Education in the United States, shows that there are now nearly 26,757 medical students being educated in 154 medical colleges. Of that number 1,219 are women; 68 of these medical colleges are attended by men only, 80 have both men and women students, and 6 are for women alone; 860 women students of medicine are receiving their education in the 80 colleges referred to above, and the remaining 359 attend as follows:

Woman's Medical College of Pennsylvania.....	175
Northwestern University Women's Medical School.....	72
Laura Memorial Woman's Medical College, Cincinnati.....	24
Woman's Medical College, Kansas City.....	23
Woman's Medical College of Baltimore.....	32
New York Medical College and Hospital for Women (Homeopathic).....	33
	359

During the Spanish-American war, Dr. Anita Newcomb McGee was in charge of the nurse corps of the United States Army, with the title of Acting Assistant Surgeon, and the rank and privileges of First Lieutenant of the United States Army. In accepting her resignation, Surgeon-General Sternberg expressed his high appreciation of her valuable services, and assured her that she had shown "excellent judgment and executive ability, and labored zealously both in the interests of the nurses and the government."

A large number of appointments in the United States is open to women, by State enactment, *e. g.*, State of Massachusetts, 1884 "From and after January 1, 1885, in each of the State lunatic hospitals, an educated female physician shall be appointed assistant physician." In the New York State code, there is a provision for the compulsory examination of the injured party in actions for personal injuries, etc., and a recent statute gives the right to the injured party, if a woman, to require that such examination be made by a woman physician.

As already mentioned, it was in 1860 that Miss Elizabeth Garrett (Mrs. Garrett-Anderson, M.D.) presented herself as a candidate before the authorities of Apothecaries' Hall, London, England. On consulting counsel, the authorities were advised that they had no power to refuse examination to any candidate who complied with their regulations. Miss Garrett, being excluded from their classes in some subjects, paid heavy fees to have these lectures delivered to her privately, passed through the 5 years of study successfully, was in 1865 registered as Licentiate of Apothecaries' Hall (L. S. A.), and so was the first woman to practise medicine in England, her name being placed on the British Medical Register. (Dr. Elizabeth Blackwell's name was also entered in the British Medical Register under Schedule A of the Medical Act of 1858, which provided for the recognition, under certain conditions, of doctors who held degrees from foreign and colonial universities prior to 1858.) Immediately afterward, however, the Board of Examiners issued a new regulation refusing recognition to certificates of lectures delivered privately, and this made it necessary for any other lady who might wish to follow the example of Mrs. Garrett-Anderson to find some other way.

The scene now shifts to Scotland. The University Court, the governing body of Edinburgh University, received in 1869 an application from 5 ladies: Miss Sophia Jex-Blake, Mrs. Thorne, Miss Edith Pechey, Miss Chaplin, Mrs. DeLacy Evans, to be allowed to study medicine, and regulations were passed permitting them to do so.

The Senatus Academicus, however, suddenly refused to arrange for the instruction of the ladies, asserting that the University Court had exceeded its legal power. A deadlock

ensued in 1871, and the five ladies had to bring an action before the Court of Session in order to be allowed to complete their university course. The case was tried in 1872 before Lord Ordinary Gifford, who decided as follows:

It is impossible to hold that ladies are students with no rights whatever, whereas males are students with legal and enforceable rights. To admit them as students and yet deny their right to be taught would be absurd. . . . And lastly, it follows that the pursuers are entitled equally as a matter of right to demand full and complete medical degrees. The right to demand graduation is the necessary consequence of the right to study at the university; ordinary medical degrees are not matters of favor or of arbitrary discretion; they are the infeasible right of the successful student.

The case was appealed to the Inner House, and in June, 1873, Lord Gifford's judgment was reversed by a majority of one. So the five ladies lost some time, labor, and money (the expenses of the suit amounted to £848), but they did not lose anything else.

When the decision was given against them, the little band of Edinburgh students went to London and appealed to public opinion and the justice of the nation. Nor did they appeal in vain. One of their chief helpers was Mrs. Garrett-Anderson. She was already well known in London society as a medical practitioner, her distinction and success in practice was a matter both of general and professional recognition and her aid was of great importance to the movement.

The cause found a champion in London. There was living then at Wimpole street, a rare and bright spirit who would have adorned any rank, profession or age—Dr. Anstie. He was distinguished alike in science and literature, and he possessed an influence remarkable for one so young. It was his delight to do justice; he had an enthusiastic love for the cause of the friendless and oppressed. In his house in Wimpole street was held on August 22, 1874, a private meeting at which the resolution that founded the London School of Medicine for Women was passed, and this meeting was attended by so many eminent persons that it was at once evident that the success of the movement was secured. Dr. Anstie was made dean, and with the aid of Dr. King Chambers and Mr. Norton of St. Mary's Hospital, the school was organized within a few weeks. But, alas; "the shadow that waits for men" waited for the new dean. This was the last act of his noble life. Before the school was opened in October he had vanished to that world where justice may be had without asking.

The second dean of the school was Mr. Norton. Dr. Anstie's friends had seen at once that their school would have to be recognized by the licensing bodies if they secured a staff mainly composed of lecturers and professors who were already on the staff of recognized schools. The wisdom of this policy is self-evident, and indeed it is stated by Mr. Robert Wilson that no other Metropolitan Medical School with the single exception of University College had then so distinguished a staff as the London School of Medicine for Women, a noble testimony to the personal influence of Dr. Anstie, and the esteem and affection in which he was held, as well as to the justice and generosity of the leaders of the medical profession in London.

The school was opened October 14, 1874, on £1,000, a remarkable instance of what can be done by personal interest and efficiency—money or no money. Twenty-three students were admitted, including the famous five ladies, one of whom, Miss Jex-Blake, "the Achilles of the movement" had courage enough for anything. She made, to the end attained, "the great contribution of a constant purpose and dominant will." Another, Mrs. Thorne, "the Ulysses of the movement," was *persona grata* to everybody, and a diplomat of no common order.

Before the 5 ladies finished their course, the two remaining mountains in their path were removed. In 1877 the energy and good management of Mr. Hopgood, of the Royal Free Hospital, and the Rt. Hon. James Stansfield, M.P., had secured to them hospital instruction in the Royal Free Hospital, and in the same year the Senate of the University of London, by a majority of 16 to 11, decided to admit women to its medical examinations and degrees.

In January, 1878, the Convocation of the University of London carried the New Charter, admitting women to all degrees

of the University, by a vote of 241 to 132, the percentage vote being as follows:

	For.	Against.
Graduates in science.....	89	11
Graduates in arts.....	80	20
Graduates in law.....	76	24
Graduates in medicine.....	21	79

This vote has been severely criticised, especially in regard to the fact that the graduates in medicine alone gave a majority against. But justice bids us remember how much nearer home the question came to medical graduates. It would make little difference personally to graduates in law, arts, and sciences; it might make a great difference to graduates in medicine. Justice bids us, too, to put ourselves in the place of those whom we criticise. Had men never been doctors, had medicine been for all these centuries the almost exclusive province of women, how should we receive the proposal to admit men for the first time to the profession? It is very possible that some of us would be leaders in a great crusade against such an innovation.

Meantime, legislation had been sought in the British House of Commons, and was promoted by Mr. Cowper Temple, Mr. Russell Gurney, Mr. Orr Ewing, and Dr. Cameron. Mr. Cowper Temple brought in his bill in 1874 "to remove doubts as to the powers of the universities of Scotland to admit women as students and to grant degrees to women." This bill was defeated in 1875 by a vote of 193 to 156. Mr. Cowper Temple, nothing daunted, introduced another bill, to permit the registration of women holding medical degrees from the universities of Paris, Berlin, Leipzig, Berne, and Zurich. In 1876 Mr. Russell Gurney, Recorder of the City of London, brought forward a bill, afterward known as the Recorder's Bill and also as the Enabling Act, empowering the British medical examining bodies to examine women. The government requested the opinion of the Medical Council upon this bill, and after debating the matter for three days, this opinion was given: "The Council is not prepared to say that women ought to be excluded from the profession." Mr. Cowper Temple's bill was now withdrawn in favor of the Recorder's bill, which became law. The first examining body to take advantage of it was the King's and Queen's College of Physicians, Dublin, and not long after the Royal University of Ireland followed. The Irish College of Surgeons took advantage of it in 1885, and the Conjoined Colleges of Physicians and Surgeons of Edinburgh and Glasgow in 1886.

But an application of three ladies in January, 1876, to be admitted to the examination for the license in midwifery of the College of Surgeons of England (a registrable license), and the advice of council thereupon that the College of Surgeons could not legally refuse to examine these three applicants, had the disastrous effect of causing the prompt resignation of the whole Board of Examiners in midwifery, so that for one and a half years there were no examiners and no examination. And to the present day, no woman has been admitted to examination by the Royal College of Surgeons of England or by the College of Physicians of London.

[To be concluded.]

Why Thinkers Live Long.—Thinkers as a rule live long; or, to put the proposition into more general terms, exercise of the mind tends to longevity. Herbert Spencer has died in his eighty-fourth year. Darwin reached his seventy-third, Sir George Stokes his eighty-fourth, Carlyle his eighty-sixth; Tyndall was accidentally poisoned at 73, but might have lived several years longer; Huxley was 70 when he died, Gladstone in his eighty-ninth year, Disraeli in his seventy-seventh. Newton lived to be 85, and Lord Kelvin is still vigorous in research in his eightieth. To a great extent the brain is the center and seat of life, what Sir William Gull called the central battery, and its stimulation undoubtedly strengthens the forces that make for vitality. Healthy exercise of either mind or body of course favors length of days, but the strivings of the thinker and writer are seldom quite of the healthy order. Darwin, Carlyle, and Spencer were victims of nearly lifelong dyspepsia, and yet exceeded three-score and ten. Pleasant exertion without pleasure; a priori, one would not expect the abstract thinker to live so happily as the man of experimental research, and experience seems to confirm the expectation. No one will question Sir James Paget's dictum that undue fatigue is a common cause of disease, but so also is indolence. What part of the human economy, mental or physical, is not made for activity?—*London Telegraph*.

1.—See *American Medicine*, Vol. V, No. 25, p. 984.

2.—**Physiology of the Sympathetic in Relation to the Eye.**—G. E. deSchweinitz draws the following conclusions from his review of the entire literature of the subject: The sympathetic should not be considered the nerve of secretion for the lacrimal gland. The dilating impulse to the iris passes from a center in the medulla as far as the second dorsal nerve, following its branch to the cervical sympathetic and through the long ciliary nerves reaches the muscular tissue of the iris. The weight of evidence favors the ciliary ganglion belonging to the sympathetic. Its removal does not influence intraocular tension. The sympathetic seems to have no relation to accommodation or changes in refraction. Section or extirpation causes a temporary fall of tension. Electric stimulation causes retraction of the nictitating membrane and proptosis. It is followed by contraction of the bloodvessels of the conjunctiva and iris. Stimulation of certain cortical areas causes pupillary dilation and all the symptoms of stimulation of the cervical sympathetic. Division of the sympathetic at the same time stops the other symptoms but not the dilation, which is supposed to be due to inhibition of the tonic action of the third nerve. Myosis is greater after excision of the cervical sympathetic ganglion than after section of the sympathetic cord. The myotic pupil responds to light stimulus, is still further contracted by eserine and may be dilated by atropine. It is uninfluenced by cocaine, which, however, may widen the contracted palpebral fissure. Sympathectomy or gangliectomy may cause increased vascularization of the eye ground, perhaps ciliary hemorrhages and alteration in the retinal ganglion cells. [H.M.]

9.—**Pulp Hypertrophy of the Teeth.**—O. Romer, in the coarse granulation tissue of which the newgrowth consists, finds nerve fibers absent, while in the pulp cavity itself and in the root canals there are numerous nerve bundles. A study of preparations has convinced him that the difference claimed between pulp hypertrophy and pulpitis chronica hypertrophica granulomatosa does not exist. The striking point in all the specimens is the richness of the blood-supply. In almost all cases there are found partly attached and partly free pulp stones and calcareous deposits, these occurring often well above the pulp chamber and the hypertrophy itself. These show cell inclusions similar to those found in the formation of secondary dentin inside the pulp chamber. The writer believes hypertrophy occurs only in pulp elements possessing great vital energy. The pulp stones are an attempt at defense from external injury. Hypertrophied pulps are frequently ingrafted with alveolar growths when coming in contact with gum tissue. Both are easily injured in chewing so that autotransplantation occurs. These hypertrophies may be excised, destroyed by arsenic, or capped as a whole with a filling or crown inserted over the cap. [H.M.]

10.—**Control of Prostitution and the Spread of Venereal Disease.**—M. L. Heidingsfeld believes that suppression of

prostitution is impossible and control impractical; it is absolutely incapable of coping with the larger and more dangerous class of clandestines, and it is powerless and impotent to materially prevent the spread of venereal diseases emanating from those directly under control. The more rational and legitimate measures for the prevention of the spread of venereal diseases are in the thorough education of our youth in the dangers that attend improper relations, in teaching that continence and abstinence are strictly compatible with the best of health, in giving instruction as to self-protection to those who believe that sexual desire must be gratified, in suppressing abortionists and in adopting regulative measures inquiring into the self-supporting character of female industrial life, and the close association of the sexes in the workroom, the enactment of legislation for segregation of prostitutes, the abolition of common drinking cups and utensils, and education in regard to unclean dental, manicure, chiropodist, and surgical instruments. The writer reports the discouraging results in Cincinnati during the regime of prostitution control. [H.M.]

Boston Medical and Surgical Journal.

January 28, 1904. [Vol. CL, No. 4.]

1. Experiments with the McGraw Elastic Ligature. FRED. T. MURPHY.
2. Differential Diagnosis of Rheumatism and the Arthritides. THOMAS J. HARRINGTON.

1.—**Experiments with the McGraw Elastic Ligature.**—Fred. T. Murphy gives a general review of experiments that have been made to ascertain the practicability of the McGraw method, and reports his own experiments. The latter were made upon 19 cats and 1 dog, and the operations included 19 gastroenterostomies and 1 enteroenterostomy. His conclusions are as follows: These experiments show that a successful anastomosis between the stomach and intestines, or 2 loops of intestine, is possible by means of the elastic ligature. The method is not applicable when an immediate opening is required. The time of the cut-out varies, depending upon the character of the ligature, the method of application, and the resistance of the tissues in any case, but the ligature will ultimately cut out. A knot at either end of the elastic loop increases the rapidity of the cut-out. The pinching of the gut by the ligature seems to cause no bad symptoms. The serous surface of the outside of the joint when completed is smooth. The anastomosis by gross or microscopic examination shows no evidence why there should be any greater tendency to contraction of the opening than with the ordinary methods of intestinal suture. The procedure causes a minimum operative risk, both as regards shock and infection. Adhesions across the opening are a possible, but not a probable complication. Extending these conclusions to practical operative work, it is his opinion that in cases in which an immediate opening of the bowel is not imperative, and in which the avoidance of operative shock is an important factor, the elastic ligature may prove to be the operation of choice in gastroenterostomy and lateral anastomosis. [A.B.C.]

2.—**Differential Diagnosis of Rheumatism and the Arthritides.**—T. J. Harrington believes there is but 1 form of rheumatism—the acute. He names 15 forms of infective arthritis, including the rheumatic, and classifies the others as arthritis deformans, osteoarthritis, traumatic, gouty, hemophilic, and senile arthritis. As a general rule all acute arthritides are secondary manifestations. In doubtful cases the probability of mixed infection must be borne in mind. The role played by the nerves is very great. If rheumatism is an infection we cannot speak of the diathesis. The cases known as chronic, should be termed recurrent. Any acute case which leaves the joint impaired or fails to yield to salicylates should be considered other than pure rheumatism. The author takes up the diagnosis of different forms, seriatim, and in detail which does not lend itself to valuable abstract. [H.M.]

Medical Record.

January 30, 1904. [Vol. 65, No. 5.]

1. The Movement of Plague in the Philippine Islands. E. L. MUNSON.
2. Report of a Case of Brain Tumor Involving the Right Lateral Ventricle. WILLIAM M. LESZYNSKY.
3. Contributions to the Obersteiner-Redlich Theory of Tabes Dorsalis. G. B. HASSIN.

4. An Antiseptic Toilet for the Hands and Vulva. DOUGLAS H. STEWART.
5. Instruments for the Production of Abortion Sold in the Market Places of Paris. FREDERIC GRIFFITH.
6. Scarlatinal Panotitis: Exfoliation of a Portion of the Labyrinth: Radical Operation. CARL KOLLER.
7. An Unusual Case of Potassium Iodid Idiosyncrasy. HENRY GATHMAN.

1.—Plague in the Philippines.—E. L. Munson reports a mortality of 83.8% for the outbreaks occurring in 4 successive years, while in Hongkong it has been 87.6%. Manila is the only place where it has a permanent foothold. The reason it has not spread is due to the fact that cascos, bancas and lorchas afford no retreats in which rats can hide and interisland steamers discharge at other ports, by means of open lighters, well off shore. Transportation by rail or vehicle is practically nil and the canals and flooded lowlands leave few opportunities for natural migration. It should be possible by comprehension and long-continued sanitary measures to exterminate the plague though infection is extremely insidious. He gives the distribution of the cases by districts, showing that it has prevailed most largely among the Chinese, along the waterfront, and in the congested mercantile districts, where the buildings are insanitary. It seems able to extend and perpetuate itself only with considerable difficulty in other quarters. This indicates where special efforts against the disease should be made. Mortality is greatest among the Chinese. It is a disease of early and middle adult life according to Manila records, but the statistics are misleading from the fact that the Chinese population consists largely of able-bodied men of working age. The preponderance of cases in males has the same explanation, and is also due to Chinese men going barefooted. [H.M.]

2.—Tumor of the Brain Involving the Right Lateral Ventricle.—W. M. Leszynsky reports the case. A girl of 19, without history of traumatism or previous infection, began to suffer with severe headache; later there was vomiting, vertigo, and in the course of a few months blindness, slight left hemiparesis with hyperesthesia, unilateral convulsive attacks of the voice, subsequently involving the arm and leg, and ultimately becoming general. The lesion was believed to be a characteristic picture of irritation. Its affecting the right Rolandic area and originating in the fauces center, and on account of the tonic character of the spasms, the lesion was thought to be subcortical. Operation was performed, but the tumor was not discovered, though permanent relief resulted from excessive intracranial pressure and the resulting irritating symptoms. The patient died, and a necropsy showed a tumor the size of a hen's egg, which appeared to spring from the inner wall of the right lateral ventricle. It was diagnosed as sarcomatous in character, probably a glioma. The author believes that had operation been performed earlier that a second operation might have located and successfully removed the tumor. [A.B.C.]

3.—The Obersteiner-Redlich Theory of Tabes.—G. B. Hassin says he discussed in a former paper the most important theories of pathogenesis of tabes dorsalis and had to come to the conclusion that the most satisfactory tabes theory is that of Obersteiner-Redlich, namely, that from the spinal roots some pathologic process extends to the pia mater (chronic inflammation, tumor, etc.), compressing the posterior roots and thus producing their degeneration, with the subsequent atrophy of the posterior columns. He now points out that lately, especially in France, there has arisen a movement among the most competent and famous neurologists in favor of the membrane theory of tabes dorsalis. The characteristic feature of this movement is the attempt to establish a connection between the pathologic processes in the spinal cord and those in the membranes. The membrane theory receives additional strength in cystoscopic examination of the cerebrospinal fluid of tabetic patients. From the standpoint of the membrane theory that tabes is a product of meningitis, we must expect that every case will be accompanied by a lymphocytosis, especially in recent cases, and this Babinski, Nagotte, and Vidal have found. [A.B.C.]

4.—Antiseptic Toilet for the Hands and Vulva.—D. H. Stewart gives what he considers the best antiseptic treatment for sterilizing hands and vulva, having compared it with 28

other methods and found it produced the best results. For mechanical cleansing he uses this: A teaspoonful of lime and 1 of powdered pumice on a saucer with wooden nail-cleaners; a basin with 2 quarts cool water mixed with 1 teaspoonful each of calx chlorata, of table salt, and of aqua ammonie, and potassium carbonate. In this basin is a nail brush. Dip the hands in this solution, take the wooden nail-cleaners and apply the pumice under and around the nails. After scrubbing, use the following solution for 5 minutes: 2 teaspoonfuls of fresh calx chlorata and 1 teaspoonful of acetic acid to the pint of sterile water. If this solution stands for 10 minutes without stirring, the necessary chemic changes are complete. In sterilizing the vulva, a solution a third the strength of the above should be used. The same for compresses on septic wounds. [W.K.]

6.—Scarlatinal Panotitis: Exfoliation of a Portion of the Labyrinth.—Carl Koller reports the case. A child of 4 developed diphtheria; the first evidence of any trouble with the ears appeared at the end of the first week; she complained of deafness, and this was followed by discharge on both sides. The deafness was absolute within 24 hours after the appearance of the ear symptoms. The child recovered from the diphtheria, but discharge continued from both ears, and there was considerable swelling of the submaxillary and cervical glands, both ear drums were perforated. In the hope of relieving total deafness, and to remove the dead bone, operation was performed upon the left side; the antrum was found filled with pus and granulations, the ossicles were disconnected, and from the middle wall of the attic a loose shell-like sequestrum was detached. This proved to be the labyrinth. The patient recovered unevenly from the operation, but there was no restoration of the sense of hearing. [A.B.C.]

5. Public Health and Food Preservatives. R. G. ECLES.
6. Some Investigations of a Bacterial Treatment of Tuberculosis. STEPHEN J. MAHER. (Continued.)

1.—Value of Patented Foods.—W. D. Halliburton says some of the milk preparations have almost no dietetic value. Many of the widely advertised farinaceous foods are even more harmful to the child than altered milk. Beef tea or "beef extract" is in no sense a food, but merely a palatable and stimulating drink, ordinarily harmless, though possibly harmful in gouty conditions. Greater or less quantities of powdered meat fibers are sometimes added. The class of food products whose claim for recognition is based upon their contents of the results of proteolysis and in which the foods are presented in the form of albumoses and peptones, have a real nutritive value proportionate to the amount of albumoses and peptones they contain. In many cases where the digestive system is at fault these preparations are of undoubted value. [C.A.O.]

2.—Hepatic Drainage in Biliary Infection.—J. B. Deever reports several cases and arrives at the following conclusions: 1. Suppurative cholangitis should be operated on before the infection injures the liver cells and before the retained bile has a chance to react injuriously upon the general organism. The presence or absence of gallstones is of no moment in deciding for early operation, though they are usually present. 2. Cholecystotomy is the operation of choice when the lesion is acute and the gallbladder has been functioning up to the time of infection. 3. Excision of the gallbladder can safely be performed in chronic calculous cholecystitis with an obstructed cystic duct. 4. Hepatic drainage must be provided for in all cases where infection is present or suspected; either through the gallbladder, or by opening the common duct or the hepatic duct. 5. Abscess of the liver is prevented and pancreatitis relieved by prompt drainage of infected bile ducts. [C.A.O.]

3.—Sterile Water Anesthesia.—S. G. Gant says sterile water properly injected is a trustworthy local anesthetic, and from experiments carried out in more than 150 cases of rectal affections radically operated on by the writer, he is convinced

that it is the most desirable local anesthetic in these operations, because it produces a sufficient degree of anesthesia, and in no instance has its employment been accompanied or followed by any of the annoying and dangerous complications which are frequently encountered when cocaine or similar drugs are used. The cases in which the method has been successfully employed include radical operations for fissure, ulceration, protruding and nonprotruding internal hemorrhoids, cutaneous and thrombotic external hemorrhoids, polypi, prolapsus ani, ordinary, complete and blind internal and external fistulas, and marginal and follicular abscesses; excision of perineal cysts, sacral dermoids, and lipomas of the buttocks; removal of foreign bodies beneath the skin and mucosa; division of the sphincter in constipation, when the muscle was so hypertrophied that division had proved ineffective; fixation of an elongated sigmoid to the anterior abdominal wall; colostomy and exploratory laparotomy. This method is not practicable, however, for extensive operations; neither is it applicable for opening the abdomen in some cases in which there is a thick layer of fat and the tissues are so loose and flabby that a proper degree of distention is impossible. [C.A.O.]

4.—Puerperal Sepsis.—Of 37 patients operated on by W. R. Pryor, streptococci were found in the uterine scrapings of 36, and in 37 they were secured from the culdesac. He believes that in every case of pure puerperal sepsis, sepsis which does not yield to simple local cleansing, peritonitis or annexal lesions are always produced, except in those rapidly fatal cases in which death takes place from septicemia before local lesions can occur. The author endeavors not only to combat the disease within the pelvis, but also to counteract the general infection. He seeks to secure this result by isolating the infected uterus between masses of iodoform gauze, and by local and systemic iodism to destroy the cocci. The operation and technique of dressing are given in detail. [C.A.O.]

Medical News.

1. Criminal Procedure against the Unlawful Practice of Medicine. HON. JULIUS M. MAYER.
2. A New Method for Performing Intestinal Anastomosis. JOHN W. KEEFE.
3. A Fatal Case of Chorea Complicated by Endocarditis, Pericarditis, and Nephritis. AUGUSTUS A. ESHNER.
4. Notes on the Widal Reaction: (1) The Question of Dilution; (2) The Influence of Jaundice. E. LIBMAN.
5. A Brief Note on the Röntgen Ray Treatment of Glandular Tuberculosis. FRANK P. VALE.

2.—New Method of Performing Intestinal Anastomosis.—J. W. Keefe describes his method, which in brief is as follows: Draw that portion of the intestine to be excised through the abdominal wound, clamp it at right angles with a $\frac{3}{8}$ -inch blade electrothermic angiotribe and apply a current of 60 amperes a minute. The compression and heat cause complete hemostasis and occlusion of the gut; clamp in like manner at the other extremity of the section to be excised. Now clamp each desiccated transverse strip with artery forces, simply as a precaution; sever the intestine by cutting through the 2 desiccated strips and clamp the mesentery to the segment to be excised in the same manner as was done to the intestine, but for a briefer space of time; cut through the desiccated strip and remove the segment of bowel. The desiccated ends of bowel are next approximated and end-to-end anastomosis is effected with a modified and interrupted Lembert suture, which is reinforced by the Cushing right-angle suture, care being taken to effect complete union at the mesenteric attachment and properly dispose of redundant mesentery. Next invaginate the intestine with the finger after the method of Loreta and use sufficient force to make a lumen through the desiccated strip; press gas and feces through the anastomosed ends to see there is no leakage. The advantages of this method are immediate hemostasis, perfect asepsis, no intestinal obstruction, no erosion of mucous membrane, no stenosis, firm union and rapid operation. The author has performed 8 of these operations upon dogs and one upon a patient and is satisfied with the results. [A.B.C.]

3.—A Fatal Case of Chorea.—A. A. Eshner reports a case in a child of neurotic heredity with slight rheumatoid

symptoms, and signs of endocarditis, in which striking relief was afforded by the administration of appropriate remedies, but in which a marked exacerbation of the choreic manifestations followed upon a severe fright, and in the sequence of which there developed pericarditis, nephritis, and myocarditis, and finally a grave anemia, with a fatal termination. Since chorea may be safely looked on as an infectious disease, it is not difficult to understand that such complications should occur, perhaps as a varied result of a common cause. How emotional disturbances act in the etiology is beyond our present knowledge. They probably give rise to certain metabolic changes. [H.M.]

4.—The Widal Reaction: (1) Dilution; (2) Influence of Jaundice.—E. Libman states that in collecting dried-blood specimens care must be taken that the blood dries before it coagulates. The reaction is better in 3 or 4 hours than immediately after withdrawing. In 1,500 specimens examined, 950 were not typhoid, and in these a Widal reaction, even in a dilution of 1 to 20, was never reported. He believes that standard of dilution should be such that the report of positive agglutination should be equivalent to labeling the case typhoid. He has sometimes had a positive result in 1 to 50 dilutions when not clearly so in 1 to 20. In some instances the lytic action of the serum is so marked that one cannot obtain a clear picture. In others, the presence of proagglutinoids is the explanation of failure. Frequently the 1 to 20 dilution is positive before the 1 to 50. Both should be used in making the test. The writer reviews the literature as to the influence of bile, and states that in his own investigations in no case could he get a positive reaction. The serums of 35 cases were tested. In those reported by others the deficiencies have been such that they demonstrate nothing to interfere with our clinical diagnosis. [H.M.]

5.—Tuberculous Glands treated by Röntgen Rays.—Frank P. Vale reports that an otherwise healthy man presented himself with a swelling in the left side of his neck. This had increased slowly for 6 months and the man had lost 55 pounds in weight; 2 months later he lost 10 pounds additional and the growth was larger. He was placed under röntgen ray treatment twice a week for 15 to 20 minutes at each sitting; no medicine was given internally. Improvement was noted at once and after 6 weeks the swelling had reduced at least half, the patient was rapidly regaining his lost weight and it was apparent that he was getting well. Vale wished to know absolutely the variety of tumor being treated and a small incision was made and 2 or 3 enlarged glands were removed, which, upon microscopic examination, were unmistakably tuberculous. The patient regained almost his normal weight. Almost a year later he returned complaining of defective speech, loss of sense of taste, left leg and arm numb and weak, memory poor, knee-jerk on the left side exaggerated and other evidences of intracranial complications. He was again subjected to röntgen ray treatment and after several months returned to his work apparently fully recovered. The author deems the case worthy of report since little is seen in literature in reference to the cure of tuberculous adenitis by the röntgen rays. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The Question of the Identity of Human and Bovine Tuberculosis.—A. v. Szekeley¹ has made a most valuable critical digest of the recent contributions to the question of the identity of human and bovine tuberculosis. First, as to the transmissibility of human tuberculosis to cattle: Park injected 4 calves subcutaneously with tuberculous sputum, and mixed such sputum with their fodder. His results were practically negative, except that in one case there was some enlargement of the lymph-glands. Moeller's feeding and injection experiments on calves likewise proved negative. The results of Cipollina, Baumgarten, and Dinwiddie

¹Cent. f. Bak., Parasit., u. Infektionskr., Bd. xxxiv, Hefte 6 and 7, December 3, 1903.

were also negative. Pearson and Gilliland, in their immunization experiments, found that young cattle could bear large quantities of human tubercle bacilli, when injected intravenously. Schottelius succeeded in producing tuberculous lesions in a cow and 2 calves, by adding tuberculous sputum to the fodder of these animals. Stenstrom obtained chronic tuberculous lesions by intrapulmonary, intratracheal, and intraperitoneal injections of tuberculous sputum. Orth produced tuberculous in a calf by the intraperitoneal inoculation of 2 pieces of tuberculous kidney obtained in the following way: Material from a human tuberculous cavity was inoculated into a guineapig, and bacilli from this animal were cultivated on brain media and carried through a rabbit, the kidneys of which served for the injection into the calf. Aside from producing local lesions, the injections of Bang into the anterior chamber of the eye proved negative. De Jong reports an interesting case: A woman whose occupation had brought her into contact with cattle developed pulmonary tuberculosis. A calf and a goat, inoculated with bacilli from this patient, which had first been carried through a guineapig, died with general tuberculosis. Hamilton and Young succeeded in 3 out of 5 feeding experiments. There was tuberculosis of the tonsils and of the lymph-glands connected with the intestinal tract. In 7 out of 9 experiments in which the material was injected subcutaneously, tuberculous lesions resulted. In 3 of these, the lungs, and in 1 the spleen, were also involved. Two inhalation experiments were likewise successful. Kossel's experiments, made with pure cultures of human tubercle bacilli, resulted as follows: Of 39 cultures examined, 19 produced no reaction in cattle; 9 caused minimal foci; 7 produced slightly more extensive, but still focal lesions; and 4—2 from cases of primary intestinal tuberculosis in children, and 2 from miliary tuberculosis in children—caused general tuberculosis in the cattle. DeSchweinitz and Schroeder's experiments with bacilli from 3 cases of generalized tuberculosis in children proved positive. These and other researches seem to settle the question as to the infectiousness of human tubercle bacilli for cattle in a positive way; although, as a rule the bovine bacilli are more virulent for cattle than are those of human origin. The observations do not justify a belief that the two organisms are of different species; the difference is merely in the degree of virulence. Schütz, in a discussion, agreed with Koch that human tuberculosis is not transmissible to cattle, inasmuch as the latter had reference not to the experimental, but to the spontaneous transmission of the disease. Not much new has been discovered regarding the morphologic differences between bacilli from different sources. Müller has found the bovine bacilli somewhat more slender than those from human tissues; slight cultural differences were also noticeable. DeSchweinitz and Schroeder have discovered that while the form of the bacilli depends to some extent upon the animal species from which it is derived, it is still more dependent upon the nature of the artificial medium upon which the bacilli are grown and upon the length of the time of cultivation. Von Szekeley also reviews the cases of skin tuberculosis that may be referred to infection with bovine tubercle bacilli, and quotes those of Lassar, Krause, Ravenel, Schütz, Spronck and Hoefnagel, and Troje. A number of cases in which the tuberculosis was attributed to the ingestion of milk from cows suffering with pearly disease is also cited. The advocates of Koch's view believe to have found a strong argument in the rarity of primary intestinal tuberculosis, but von Szekeley contends that this point really has no weight; for (1) the cases of primary intestinal tuberculosis are not very rare, (2) the intestine has a fairly strong resisting power against infection with tubercle bacilli, and (3) the bacilli may enter the organism through the intestine without the latter's becoming diseased. In feeding experiments on animals, observers have discovered that the intestines

may escape infection, while the lungs and the bronchial glands become the seat of tuberculosis. In concluding, von Szekeley states, concerning the essential point of the discussion, that while the question of the identity of human and bovine tuberculosis can not be considered as definitely settled, the view expressed by Koch that bovine tuberculosis is not dangerous for man cannot be maintained.

REVIEW OF LITERATURE

Blood-pressure and the Exchange of Fluid Between Blood and Tissues.—O. Hess¹ has investigated the question of the influence of variations in blood-pressure on the filtration of fluid from the blood into the tissues and vice versa. The concentration of the blood is affected only in the venous system by variations in pressure. Before the blood reenters the arterial system, it either receives or gives off fluid, in order to bring the concentration back to the normal. This adjustment of concentration takes place in the lungs, where the blood is brought into intimate association with the lymphatic system. The great factor which makes this adjustment possible in the lungs is the independence of the vasomotor tone in the pulmonary circulation; the variations in pressure, which occur in the greater circulation, have little or no effect on the pulmonary vessels. The liver also seems to take part in restoring fluid to the blood, where the latter has become more concentrated as a result of increased blood-pressure. [B.K.]

Pneumothorax.—C. P. Emerson² presents a most thorough and exhaustive historic, clinical and experimental study of this condition. His method of presenting the literature of the subject is admirable when the necessary space is at the disposal of the writer. Appended to each of the 358 references is an abstract of the article giving the salient clinical and pathologic data which it contains. This furnishes a very valuable treatise on the subject in question and will prove a boon to all future investigators along this line. Emerson then reports in detail the cases of pneumothorax, 47 in number, occurring in the service of the Johns Hopkins Hospital. Of these, 22 were certainly due to tuberculosis, 18 being males and 4 females. There was no preference for sides, 11 being on the right, 11 on the left. Bronchiectasis was responsible for 2 cases, only 11 other cases being recorded in literature. One case was certainly, another possibly, due to metastatic abscess of the lung. Brief notes of 9 cases of gunshot and 5 of stab wounds of the lung not followed by pneumothorax, are given. Experiments on dogs lead to the conclusion that gas analysis has very little value in the diagnosis of the condition of the fistula. Among the points leading to this assertion are: 1. There is a rapid accumulation of CO₂ in the pleura after death, this ruling out the majority of the analyses previously published. 2. The presence of a purulent exudate is an important factor in determining the composition of a gas. 3. Postmortem accumulation of CO₂ may explain the high tension of the gas which hisses from the chest on the autopsy table. The article closes with a brief discussion of the course, symptoms, diagnosis, prognosis and treatment of pneumothorax. [A.G.E.]

Paralysis of Multiple Cranial Nerves.—O. Aronsohn³ reports an interesting case of palsy of the facial, trigeminal, and auditory nerves. The patient, a man of 30, after exposure to a cold wind, developed swelling of the left face, which, however, disappeared in a day. In the course of 2 weeks there appeared the characteristic symptoms of paralysis of the facial and trigeminal nerves. A constant loud humming was heard in the left ear. Previous to his exposure his sense of hearing was perfect, but he now noticed that he was unable to hear anything with that ear. The author was able to exclude brain tumor, lues, or any organic constitutional disease. On account of a troublesome vertigo, potassium iodid was prescribed. This treatment was promptly followed by disappearance of the symptoms, due to paralysis of the facial and trigeminal nerves. This seemed to indicate strongly that syphilis at the base of the brain was the cause of the paralysis. No change, however, occurred in the symptoms caused by the diseased state of the

¹ Deut. Archiv f. klin. Med., Bd. lxxix, p. 128.

² Johns Hopkins Hospital Reports, Vol. xl, 1903.

³ Berliner klinische Wochenschrift, November 9, 1903.

auditory nerve. The potassium iodid, together with inunctions of mercury, were continued for several months, but with no improvement in the left ear. Aronsohn concludes that the auditory nerve was diseased in the same manner as the other nerves, but to a greater extent, and that when that nerve is once paralyzed it is irreparable. [W.E.R.]

Treatment of Renal Calculus.—The treatment of this condition divides itself into the treatment of renal colic and that of the diathesis which provokes the formation of renal calculus. For mild forms of renal colic, Ch. Vinay¹ merely employs a warm bath at a temperature of 37° C., prolonged for an hour, and followed by a cold sponge. For more severe cases morphin is required, but may sometimes be substituted by a very hot bath, 40° C. to 42° C., for 15 to 20 minutes. For the treatment of renal lithiasis, Vinay employs piperazin, or its derivative, sidonal, and urotropin. Sidonal is given for a week in doses of 3 gr. to 5 gr. 3 times a day; followed by urotropin, 7.5 gr. 3 times a day for a week, and then some mild mineral water for the third week. The alkaline treatment may also be employed, using the salts of sodium, potassium or lithium. The best diuretics to be employed are water and milk. Water is best taken in the form of some mild, noncarbonated, mineral water between meals. As to diet, the green vegetables are especially recommended, and the starchy vegetables restricted. It is useless to draw a distinction between white and red meats. Fruits are also recommended. The diet should consist of one-fourth meats and three-fourths vegetables. Exercise should be moderate, and not forced to the point of fatigue. [B.K.]

The Age Incidence of Tuberculosis.—In an article written from the standpoint of the relation of tuberculosis to life insurance, T. D. Lister² furnishes statistics that controvert the idea usually held regarding tuberculosis as being principally a disease of the young. By a diagram he shows that the deaths from tuberculosis form a band of practically even width throughout the various decades of life while that of every important group of death-causes begins as a minute wedge, and grows constantly broader from youth to old age. A slight falling off in the rate from tuberculosis is seen in the later years, but this is ascribed to the fact that tuberculosis may be the termination of chronic diseases, and not be recognized as the terminal event. The 3 elements to be considered are hereditary vulnerability, acquired vulnerability, and the danger of infection. The first decreases with age, the second increases with age, and the third remains constant. [A.G.E.]

Comparative Value of Oral and Rectal Temperatures in Tuberculosis.—T. N. Kelynaek and S. R. Williams³ conclude that oral temperatures taken during rest are reliable, but when taken during or shortly after exercise, they are not trustworthy, on account of local conditions influencing the temperature of the mouth. Rectal temperature is usually higher than that in the mouth during rest, and is always considerably higher during or after exercise. However, for practical purposes the authors found it sufficiently accurate to take the temperature by mouth during a state of rest. [B.K.]

Yellow Fever and the Stegomyia.—G. Sanarelli⁴ presents the attack on his views and laboratory methods made by Professor E. Perroncito,⁵ of Turin. The objections by the latter are personal rather than scientific. The views quoted by Perroncito are by unknown men, and as to the charge that Sanarelli left off his studies unfinished, and with the valueless protective serum as the only result, it may be said that this matter must for the present give way to other affairs, "since alone it is not worth a life study." Sanarelli asserts that with the publication of his treatise in 1897 the etiology of yellow fever is determined. Seven years went into its preparation; he is not to be censured for haste or lack of reasonable investigation. Sanarelli joins the verdict of the recent medical congress at Rio Janeiro, which opposes by all its scientific element the idea that the stegomyia is an essential factor in the etiology of yellow fever, although Professor Perroncito believes its conclusions the reverse. The author is sustained by Brazilians of

repute. Attention should be drawn to the paper of Rocha Faria (Professor Hygien., Rio Janeiro), an epitome of which the author includes. Credit of initiatory work belongs to Richardson, of Philadelphia, and Jones, of New Orleans, in 1878. Since then the best work is recorded by C. Finlay, Le Dantec, Sternberg, Sanarelli, Reed, Agramont, and G. B. Lacerda. Perhaps most interesting is the work of Ivo Bandi, and this is very strongly appreciative of the role played by *B. icteroides*. The results of work in Cuba are in distinct opposition, and to be viewed with hesitation. Sanarelli deplors the misrepresentations in his own country, and the injustice which has arisen from "aged peripatetics and antiquated academicians." [T.H.E.]

Results in India of the Haffkine Prophylactic.—B. R. Slaughter¹ gives the results of a personal investigation in India of the results obtained from the use of the Haffkine prophylactic in checking the spread of plague. The benefits of that material are thus summarized: (1) It renders a person immune for 3 months; (2) it acts within 24 hours; (3) when inoculation is given in the incubation stage of the disease, that is, before signs of plague appear, it has in many cases the power to abort the disease; (4) inoculation has no effect on other diseases, except possibly eczema, which appears to be benefited by it; (5) inoculation confers a high degree of immunity and greatly reduces the number of plague attacks; (6) when, in spite of inoculation, a person is attacked, his chances of recovery are greatly increased. The principal reason why, in spite of England's persistent efforts to exterminate the plague, so little has been accomplished is said to be the laxity of the natives in carrying out the necessary precautions. [A.G.E.]

Antithyroid Serum.—J. Lepine² has succeeded in immunizing the goat against thyroidism, the process being, however, long and difficult. The serum of the immunized animal produces no bad effects in the dog, if used in doses under 20 cc. and at several days' intervals. In this dose the serum seems to diminish the function of the thyroid gland. The author believes that this serum may be employed with benefit in cases of exophthalmic goiter, but must be used with care. [B.K.]

GENERAL SURGERY

A. B. CRAIG MARTIN B. TINKER C. A. ORR

EDITORIAL COMMENT

Gastric Tetany.—The surgery of the stomach has been developed almost entirely within the past twenty-five years, and the number of cases successfully treated by operation has been steadily increasing. Almost every practising physician is familiar with the brilliant results which have been obtained recently in the surgical treatment of gastric ulcer, and the numerous distressing gastric symptoms resulting from benign obstructions of the pylorus which have been relieved. Gastric tetany is one of the less frequent affections of the stomach, the symptoms of which, perhaps, have not been generally recognized. In a recent paper on this subject, Mr. B. G. A. Moynihan,³ of Leeds, Eng., gives a very interesting and satisfactory discussion of this somewhat unfrequent affection. He uses the term gastric tetany to include all cases of tetany and tetanoid spasm associated with or directly due to disease of the stomach, and he believes that it is more common than is generally known. In the early stages the patient complains of peculiar numbness, prickling, tingling, or a feeling of pins and needles in the extremities; coldness, heaviness, or a feeling of fatigue are also mentioned. Formication frequently follows vomiting, and in almost all fatal cases severe and uncontrollable vomiting precedes the attack. As formication increases, a tetanic contraction of muscles occurs, fixing the fingers and hand, and often the muscles of the entire forearm and arm. The muscles of the face, jaws, neck, and abdomen are involved at times. The other symptoms of the affection are fully described, but these

¹ Lyon Medical, January 3, 1901.

² The Practitioner, November, 1903.

³ British Medical Journal, October 24, 1903.

⁴ Il Politecnico, Rome, November 21, 1903.

⁵ American Medicine (abstract), Vol. vi, No. 21.

² Lyon Medical, November 20, 1903.

³ Boston Medical and Surgical Journal, Vol. cxlix, p. 501.

are the most important indications of the disease. The general effect of the attack varies with the severity and duration of the seizure. Records of many writers show that it is an extremely serious and often fatal disease. Albu reported 31 deaths in 40 cases; Bouveret and DeVic, 18 deaths in 23 cases. Moynihan believes that in almost all cases of gastric tetany there is a grave mechanical obstruction to the passage of food, which causes dilation and hypertrophy of the stomach, and the only rational treatment is to relieve the obstruction by operation. Gastroenterostomy is the method of choice in simple cases, and if promptly treated gastric tetany of the fatal type will soon be a forgotten disease. In three cases out of five in which he has operated, duodenal ulcer associated with gastric ulcer was found. The very high mortality in cases treated medically and the comparatively slight danger of surgical treatment seem to indicate the wisdom of Moynihan's suggestion. Gastroenterostomy is an operation which has been performed with increasing frequency and with most satisfactory results in a large number of patients suffering from various forms of gastric indigestion, and the mortality has been greatly reduced in recent times from 65.7%, which Haberkant reported in a series of cases operated upon between 1881 and 1885 to 33.9%; in a series collected by Chlumschij between 1891 and 1896, while recently Mayo has reported a mortality of only 10% in a series of 80 cases in which he operated personally, and Dalziel reported 30 operations with only one death. This great improvement in statistics is due solely to improvements in operative methods and antiseptic technic. In conditions so grave as gastric tetany the indication for operation would be definite even were the mortality of gastroenterostomy much greater.

REVIEW OF LITERATURE

Experimental Studies of Antiseptic Dressings.—Noetzel,¹ in his investigations, infects freshly made wounds of rabbits with anthrax; one is placed with the control without a dressing, one with a dry dressing, one with dressings moistened in salt solution, and another dressed with moist mercuric chlorid 1-1,000. Each experimental animal had its corresponding control inoculated with the same culture. The results of his experiments were as follows: All the undressed animals died; of the 7 whose wounds were dressed with dry gauze, 3 died; of the 7 dressed with moist salt solution gauze, 2 died; and of the 7 dressed with moist bichlorid, 3 died. Noetzel says dry gauze succeeds as well as the moist in absorbing virulent anthrax bacilli so that no infection results, and from his experiments neither evinces a decided advantage. He found in the moist gauze the bacteria had reached the outer layers of the gauze from the infected wound, whereas in the dry dressings they were found in the layers near the wound only. In the sublimated gauze neither the anthrax bacilli nor the bacteria of the surrounding skin remained viable. [J.F.]

Intestinal Anastomosis, Occlusion of a Portion of the Intestine, and Death.—R. W. Murray² reports that a boy of 12 was presented who had been well until 3½ years before, when for intestinal obstruction a surgeon had performed enterostomy to the left of the median line. Relief was afforded for a short time, when obstruction again occurred, and enterostomy was performed on the right side. Since then life had been miserable, all the feces escaping from the last enterostomy, and a marked prolapse occurring at each opening. Murray now operated, removing the prolapsed intestine and closing the orifice at the site of the first operation. Some 3 months later operation was again performed, and the small intestine at the site of the last operation was anastomosed to the transverse colon, thus occluding a portion of the ileum, the cecum, and ascending colon. Though the bowels had not moved naturally for over 3 years, they now moved naturally, the patient gained much in weight, and did well for almost 2 years, when distension of the abdomen began, increased steadily for several

weeks, and the patient died. Necropsy showed the occluded portion of the intestinal tract greatly distended with mucopurulent fluid. He says the case demonstrates the danger of retaining in the abdomen any portion of the gut occluded at each end. [A.B.C.]

Tuberculosis of the Hernial Sac.—R. Lewisohn¹ has collected from the literature 58 cases of this affection, which he briefly describes and summarizes, together with 4 cases of his own. The principal symptoms on which a diagnosis may be made are: The presence of a tuberculous peritonitis; reducible fluid contents of the sac; larger nodules on the floor of the sac, separable from the spermatic cord and testicles; smaller nodules arranged in the form of a rosary along the inguinal canal. The prognosis following operative treatment is especially good, both in regard to recovery from the hernia and from the tuberculous affection. [B.K.]

Pathogenesis and Therapy of Acute Hemorrhagic Pancreatitis.—Bunge² reports a case which was cured by operation. The hemorrhage was diffused in the peripancreatic tissue and was accompanied by diffuse fat necrosis. He found a serosanguineous exudate in the peritoneal cavity; the exudation, he says, began in the omental bursa, and was followed by fat necrosis of the gastrocolic ligament, and by perforation of that structure. If the anterior wall of the lesser omentum is intact he cuts it, removes the exudate and packs the bursa with iodoform gauze; secondary perforation of the posterior wall is guarded against by raising the omentum, colon, and the stomach, and packing that region with gauze. Bunge inclines to the view taken by Hahn, who operates in the early stages of this condition. Bunge says the operation should be done early, before the entrance of bacteria from the intestines complicates the process. If the exudate in the lesser omentum is already infected, and if there is exudate free in the peritoneal cavity, the time for operation is passed. He says we are still deficient in diagnosing this condition; it must be made upon the frequent attacks of acute colic and the early vomiting of the small intestinal contents. Acute hemorrhagic pancreatitis differs from peritonitis by a lack of tenderness and rigidity of the abdomen in the first. As to the cause of acute hemorrhagic pancreatitis Bunge says we know practically nothing. The fat necrosis is in the majority of instances due to fermentative action of the steapsin of the pancreatic juice upon the neutral fat of the peritoneal cavity. [J.F.]

Protruding Auricles Treated by Operation.—T. G. Ouston³ reports that a boy of 11 was brought with the request that the appearance of his ears should be improved. The condition was congenital, and the margins of the pinnae curled forward considerably anterior to a vertical transverse plane through the centers of the external meati. Their posterior surfaces were smooth and convex, instead of presenting the normal depressions. They had a large amount of spring, the cartilage not even allowing temporary molding into the normal shape. The ears were operated on under ether separately, a "D" shaped piece of skin ½ in. by ½ in. was dissected up and removed from the prominent convexity of the posterior surface. The corresponding underlying piece of cartilage was cut round vertically to its surface, and the separation of its anterior surface from the skin effected by a small periosteal knife, the attachment being more intimate than on the posterior aspect. The pinna was now flaccid, and on pressing it backward onto the skin over to the mastoid, an accurate impression of the raw surface was mapped out in blood. This area of the skin was removed, and the posterior edges of the 2 raw surfaces united by fine sutures. With the left ear, the removal of the 1 piece of skin and cartilage proved sufficient. In the right, sickle-shaped strips of skin and cartilage had subsequently to be removed from the still overhanging upper margin. The illustrations are given, showing the admirable correction. The author states that in severe cases anything less than free removal to the extent of taking all spring out of the auricle will result in failure. [A.B.C.]

Dislocation of the Carpal Scaphoid.—Leonard W. Ely⁴

¹ Mitt. a. d. Grenzgeb. d. Med. und Chirurg., Bd. xi, Heft 5, p. 667.

² Arch. f. klin. Chir., 1903, Bd. lxxi, Heft 3.

³ British Medical Journal, July 4, 1903.

⁴ Annals of Surgery, July, 1903.

¹ Arch. für klin. Chir., 1903, Bd. lxxi, Heft 1.

² Lancet, August 22, 1903.

reports that a man of 25 sustained an injury to the right wrist and the lesion was diagnosed as a crushing of the tendons of the wrist and hot applications applied. When seen the next day, the wrist was much swollen, motion caused much pain, and the case was then diagnosed as Colle's fracture, and the patient given an anesthetic for reduction. Under ether, crepitus could be distinctly obtained in the wrist. By manipulation, the scaphoid could be easily dislocated on the dorsum of the wrist and by pressure could be replaced. From this symptom the diagnosis was made. Skiagram taken, showed a slight dipping forward of the scaphoid, chipping of the styloid process of the ulna. Dislocation of the carpal bone was unmistakable. The treatment was by anterior and posterior molded plaster splints, the posterior reaching to the end of the phalanges and the anterior to the metacarpophalangeal joint. Patient recovered with a good degree of motion in all directions. [A.B.C.]

Early Massage and Passive Motion in the Treatment of Fractures and Sprains.—D. N. Eisendrath¹ urges the use of more radical methods in the treatment of fractures. He believes that by the judicious, early use of massage and active and passive motions that the wasting of muscles and the stiffness of joints and tendons after fractures can be largely decreased. In the larger cities it will be best for the physician to secure the services of a masseur or masseuse, but where such aid is not to be obtained the physician himself can carry out the treatment. The method to be preferred is that of rubbing the limb principally with the thumb and finger tips of one or both hands toward the axilla in case of the arm and in the lower extremity toward the groin. At first they should be very light and last only 3 to 5 minutes. Later they can be made more vigorous and 10 minutes in duration. Hot application for 10 minutes previous will make the massage much less painful. The principal varieties of fractures of the long bones are considered separately, with the indications for massage. In the case of fractured patella, massage is begun within 48 hours after the injury has been received. The contraindications to the use of early massage are tendency to displacement of the fragments, compound fractures (until the wound is healed), when the condition of the skin permits of infection, and the presence of fragments which project but which do not penetrate the skin. [A.G.E.]

Exposing the Hip-joint by Larghi's Curved Incision.—A. von Bergmann² says from the number of cases treated it is impossible to judge whether an attempt to replace a congenital dislocation of the hip in adults is advisable. To draw any conclusions from the case successfully treated by him would be imprudent. If the dislocation is painful and causes distress, v. Bergmann advises operation, but impresses upon the patient the long-continued after-treatment and the possibilities of an unsuccessful operation. If an operation is undertaken upon a congenital dislocation, v. Bergmann believes the incision of Larghi is, in spite of its length, the best to be recommended, even if the acetabulum is developed only feebly. Since by this method replacement was successful in a patient of 22 years, one can commend it in younger individuals. [J.F.]

Ganglion of the Palm of the Hand.—Franz³ removed 3; 1, supposedly ganglion, was an encysted sesamoid bone, but the patient felt something burst at the site of the tumor the evening before the operation. Operation was refused in 1 case; in another the tumor disappeared by firmly grasping the sharp edge of a chest. The seventh case was found to be a thickened tendon sheath. He believes that through the constant exertion of pressure in the palm, many ganglions are bursted before they manifest their presence. Trauma, either acute or chronic, can be traced as a cause in 6 of his cases. Microscopic findings corroborated this view. When the ganglion is barely perceptible he recommends fixing the affected part in a pasteboard splint for 3 or 4 weeks. When it can be felt, he bursts the ganglion by pressure, and when this fails he extirpates. [A.B.C.]

Surgery of Penetrating Gastric Ulcer.—Hans Lorenz⁴ reports 2 cases of this condition in women of 52 and 57 respectively who were operated upon. In both cases the ulcers were

torn during the operation, but in spite of this the ulcers healed in a comparatively short time. In the first case the perforation was insignificantly lessened by a suture; in the second this procedure was not carried out, and instead a drainage-tube was inserted in the stomach, through which the patient was nourished. In both cases finally gastroenterostomy was done. [J.H.W.R.]

The Effects of the Röntgen Rays upon a Sarcoma of the Skull.—Krogus,¹ after treating an inoperable sarcoma for 14 days, found the second largest tumor and a number of the smaller ones had disappeared. One and a half months after instituting treatment, the largest tumor disappeared. Krogus persisted with the treatment for another month and saw the patient 4 months after that date; there was no evidence of a recurrence. Krogus says one can not conclude from this that all malignant tumors are curable with this treatment, but he is convinced that some cases are benefited, and that it should be tried in all cases, even if only one case in a hundred derives benefit from the treatment. [J.F.]

Surgery of the Ureter.—P. J. Freyer² holds that only when a stone is impacted in the lower end of the ureter, within 1 or 2 inches of the bladder, can it be differentiated from a stone in the kidney. A skiagraph may afford strong evidence, but it is less satisfactory than when applied to renal stone. The 3 situations at which impaction is likely to occur are: A point 5 cm. (2 in.) from the commencement of the ureter; at the brim of the pelvis; and at the vesical end of the canal. He reports somewhat in detail cases under the following captions: Calculus impacted in the left ureter 5 cm. (2 in.) below the renal pelvis, successful ureterolithotomy; calculus impacted in the right ureter 10 cm. (4 in.) below the renal pelvis, successful ureterolithotomy; calculus impacted in the ureter 2½ cm. (1 in.) above the vesical orifice, successful vaginal ureterolithotomy; calculus impacted in the lower end of the ureter, successful retroperitoneal ureterolithotomy; diverticulum of the ureter, forming a cystic tumor in the bladder wall, containing 2 calculi, successful suprapubic cystotomy; calculus impacted at the vesical orifice, successful suprapubic cystotomy. If the symptoms of renal or ureteral stone exist and stone cannot be located in the lower end of the ureter, then it is the recognized rule in surgery to do a lumbar nephrotomy. Open the kidney, and if the stone is not in that situation, pass a probe down the ureter, locate the stone, extend the lumbar incision parallel to Poupart's ligament and reach the ureter postperitoneally. Emphasis is laid on the intelligent use of the cystoscope. [A.B.C.]

Appendicitis Caused by Pin-worms.—Of all intestinal parasites found occasionally in removed appendices, thread-worms are the most infrequent. A. F. Kablukoff³ reports a case of catarrhal appendicitis which came to the operating table. From the removed appendix 4 pin-worms, all females, crawled out, and showed signs of unmitigated vitality. When we remember the disturbances caused by pin-worms in the rectum or in the vagina, we need not be surprised at their role in producing a catarrhal inflammation of the appendix. Indeed, we may surmise that many cases of appendicitis attributed to fecal concretions are in reality due to intestinal parasites, as contended recently by Dr. Oppe. [L.J.]

The "Gastrophore" as an Assistant in Operations upon the Stomach and Intestines.—Narath⁴ says this instrument, by fixing the stomach acts as an assistant by coaptating the walls of the organ prevents the escape of stomach contents, and also prevents hemorrhage. He further says the operation can be done easier and quicker, and if a button be used to anastomose it cannot fall into the stomach. The instrument consists of 2 arms united at one end as a hinge, upon the other end 1 arm contains a convex plate, and the second a ring. The arms can be fixed at any angle by means of a set screw. The convex plate is placed upon the posterior surface of the stomach, the ring upon the anterior, then the arms are pressed together and held in position by the set screw. In this position the mucosa of the posterior wall is in close contact with that of

the anterior, therefore Narath says, one must be careful when cutting the one wall that the other is not injured. [J.F.]

Buried Unabsorbable Ligatures.—C. Hamilton Whiteford¹ calls attention to the frequent sinus formation caused by unabsorbable ligatures, and the shedding of the same, months, and often years, after healing by first intention. In explanation of such occurrences, he says we are asked to believe that the ligatures were infected at the time of operation, but that the infecting bacteria did not prevent sound union by first intention, and these bacteria after lying dormant for weeks, months, or even years, have suddenly broken out and caused the ligatures to be shed. What actually happens is that the ligature uniting the soft tissues, which are constantly changing position, soon cuts its way loose and lies relatively free. It then becomes encapsulated, or it shifts its position to a place of least disturbance, and there becomes more or less encapsulated. So far the process is an aseptic one, and it would remain so but for the special affinity of bacteria for damaged tissues, i. e., the tissues surrounding the foreign body. The bacteria may come from the blood, or they may be the normal bacteria in contact with the tissue affected, as from the bowel. The only safe and rational way to avoid this trouble is to use only aseptic absorbable suture and ligature material. We now have such a material in catgut prepared with formalin or xylol. [A.B.C.]

Descending Tuberculosis of the Urinary Apparatus.—There are 2 forms of urinary tuberculosis, the ascending form, in which the kidney is infected from the bladder, and the descending form, in which the kidney is primarily infected through the blood. Guyon and his school have taught that the ascending form is the more common. Modern surgery has shown, however, that the descending form occurs much more frequently. A. Goetzl² reports 2 cases of the latter, in which the diagnosis of primary renal tuberculosis was made by careful examination. Cystoscopic examination in such cases will show that the bladder is not seriously affected, while the mouth of the ureter on the diseased side will show some inflammatory changes. The ureter should be catheterized, and the urine injected into guineapigs in order to make the diagnosis. [B.K.]

Radical Manipulation of Intestinal Invagination.—v. Elselsberg³ operated upon 13 patients, 11 adults and 2 children; 7 were chronic, 3 subacute, and 3 acute. He says it is not always possible to differentiate between the acute and the chronic. Twice the invagination was of small intestines only; 10 times it was at the ileocecal valve, and once at the sigmoid flexure. As causes of conditions, he says, there was present polypoid tumor 3 times, carcinoma of the sigmoid once, cicatricial stricture once, lymphosarcoma once, an ulcer at the head of the invagination that proved to be a tumor microscopically, once; in the remaining 6 cases there was an abnormally long mesentery. Pain was present in all his cases; vomiting in all but 3; diarrhea in 9; in 5 of these the stools contained blood; in 4 there was constipation; meteorism was always present; in 10 cases a distinct tumor was palpable; where the sigmoid was invaginated the tumor was palpable per rectum. He did 12 total resections; one died with gangrene and perforation soon after the operation; one died 3 weeks and one 6 weeks after operation of marasmus. He prefers total resection since with simple disinvagination there is a tendency to recurrence. [A.B.C.]

Have the Locality and Surroundings an Influence upon the Recurrence of Malignant Disease?—D'Arcy Power⁴ raises this question and cites a number of apparently nearly parallel cases, so far as could be judged, showing that in the one case the patient returned to the former home-life and environments after the primary operation, and speedy recurrence followed; while in the other case the patient similarly afflicted left his or her old environments, took up new habits of life, sought diversion of work in new places and amid different surroundings, with the result that recurrence was apparently much longer delayed, or did not take place at all. He admits that there is no direct proof that the change had an influence on the pathologic process; we can only judge from inference, and he

makes an appeal for other surgeons to make observations along this line that correct judgment may be rendered from a large compilation of facts. [A.B.C.]

A Few Modifications in the Radical Operation for Inguinal Hernia.—Petrulis¹ says in the first modification the skin incision is made according to Bassini, the aponeurosis of the external oblique is split longitudinally, the internal oblique and the transversalis are not cut, but the cremaster and the tunica vaginalis communis are incised. The sac is isolated and detached as far as the internal ring. The sac is drawn out, twisted, and then 2 sutures are introduced high up—one in the internal and the other in the external half of the sac. Both ends of each suture are brought out through the abdominal wall a little above and external to the internal ring; this process unites the sac to the abdominal wall and dislocates the internal ring upward and outward. After the sutures are tied the sac is cut off a short distance below them. He closes the wound by a double loop mattress suture and gives egress to the cord in the lower angle of the wound. He uses metallic sutures entirely. His second modification is not applicable to corpulent individuals. It differs from the first in that he uses a single loop mattress suture to close the abdominal wall instead of a double. [J.F.]

Gunshot Wound of the Longitudinal Sinus.—B. F. Curtis² reports that a man of 42 received a pistol wound in the back of the head, the ball coming from below and to the side. The ball penetrated the skull but there was not much bleeding at the time. There was complete blindness of the right half of the visual fields when he was brought to the hospital and at operation. In the attempt to remove the large fragment of bone there was profuse and violent venous hemorrhage. The wound was packed with gauze, 2 trephine openings were made adjacent to the wound, and the bridge of bone broken down to make one large opening. Hemorrhage was again violent. On being controlled by the gauze pressure it was found there was a large wound in the longitudinal sinus near the torcular herophili. An unsuccessful attempt was made to close the opening by suture, but packing had finally to be resorted to. The subsequent progress of the patient was rather stormy, his mental condition being unsatisfactory and various eye symptoms appearing. At the end of 15 days all the packing was removed. A skiagraph which afterward proved to be faulty, showed the ball to the right of the median line. Delirium developed. A subsequent operation was performed and an unsuccessful search made for the ball. The patient slowly recovered and was discharged from the hospital after 3 months. The right half of each field of vision was cut off vertically and about 5° to the right of the median plane in each. A subsequent skiagram taken carefully, showed the ball to be on the left of the median line, and accounted for the unsuccessful search made for it at an earlier time. The lessons the author would draw from the case are, the dangers from excessive hemorrhage, in the attempt to remove fragments of bone in the vicinity of the longitudinal sinus, and the utmost importance attached to the care in making skiagraphs, having the plates so marked that there is no possibility of mistaking one side for the other. [A.B.C.]

Rupture of the Bladder.—W. Nobe³ has collected 32 cases of traumatic rupture of the bladder, and added to them 3 occurring in his own practice; 21 of these, including his 3 cases, were operated upon; 18 (85.7%) recovered; of the 14 not operated upon, only 7 (50%) recovered. Of the 3 cases in which death followed the operation, one was operated upon on the fifth, another on the eighth day; both died of sepsis; the third died as the result of hemorrhage. He concludes, that the best and most conservative method of treatment in all cases, where vesical rupture is strongly suspected or diagnosed, is the operative method. The sooner the operation is performed the better is the prognosis. In extraperitoneal ruptures he advises an incision as in suprapubic lithotomy; he closes the ruptures, if they can be found easily, he tampons if not; he drains the wound, inserts a permanent catheter, and closes the abdominal wound. In intraperitoneal ruptures he searches until he finds the ruptured spot, sutures it, and closes the wound. [E.L.]

Carcinoma of the Intestines.—v. Mikulicz¹ reports 106 malignant tumors of the intestines. Three sarcomas of the small intestines, 2 sarcomas of the colon, 1 epithelioma of the transverse colon, 5 carcinomas of the small intestines, and 95 of the large intestines. The higher in the intestinal tract the situation of the tumor, the more pronounced are the manifestations. An intestinal tumor may run a latent course, again it may produce indefinite symptoms; then again it may produce stenosis, and finally obstruction. These conditions may all be produced at identical situations in different cases. Ulceration and bleeding usually accompany the condition; bleeding and pus when the tumor is at the sigmoid, as a rule, when the neoplasm is high up. These complications, unless profuse, are often concealed. When peritonitis follows, the infection occurred at the time of the operation, or through an insufficiency of the sutures. The danger of primary peritoneal infection through the opened intestines is greater than is usually admitted. A patient with acute intestinal obstruction is, in consequence of an intestinal intoxication, so devitalized that he cannot resist even a minimum infection. The same is true of chronic obstruction, but in a less degree. [A.B.C.]

The Origin of Foreign Bodies in the Knee-joint.—Boerner² discusses the origin of foreign bodies in the knee-joint very fully, giving a bibliography, the results of clinical experiences and microscopic examination of a number of specimens. He finds, on microscopic examination of 28 specimens, that some of these foreign bodies are composed of bits of cartilage and bone from the joint surfaces. Some observers have maintained that all the foreign bodies of the knee-joint were of this kind; others have believed that they arose almost exclusively from disease processes, particularly arthritis deformans. Boerner finds microscopic evidence to support this latter theory also. Of the foreign bodies composed of bone and cartilage some were found in cases in which there had been no previous injury to the joint. In 4 cases at the time of operation small fatty tumors were found which had been mistaken for foreign bodies. In 1 other case a thickened fibrous mass, a fringe from the joint capsule had caused the symptoms, and in 2 cases a small piece of the semilunar cartilage had worked free in the joint. [M.B.T.]

Perforation of the Gallbladder.—H. A. Ledlard³ reports that a male patient of 70 was found with a distended abdomen, pain, vomiting, and all the usual symptoms of intestinal obstruction. After 3 days the patient died, and necropsy showed an abscess in the region of the gallbladder, with perforation of that viscus, general peritoneal infection, and 515 stones of various sizes, all small, in the gallbladder. The combined weight of the stones was 1½ ounces. The patient had not suffered from jaundice or biliary colic and nothing pointed to hepatic involvement. Another case is reported. The patient was a woman of 47, who had experienced attacks of biliary colic at various times for 3 years. The attacks usually yielded to hot applications and morphia and were not attended by jaundice. In the present attack there were jaundice, fever, and tenderness in the region of the gallbladder, but no tumor. A week later the abdomen was much distended, and a tumor in the region of the gallbladder was the size of an adult head. Incision in the middle line, the matted omentum showed a recent peritonitis, much bile-stained fluid escaped. The gallbladder, in a mass of omentum, contained a perforation on its anterior surface and a small stone lay outside the viscus. The opening into the gallbladder was enlarged and 13 additional stones were found. The perforation was closed by invagination and suture, the abdominal cavity thoroughly flushed, and the laparotomy wound closed without drainage. The patient recovered. [A.B.C.]

Operations upon the Choledochus Duct on Account of Narrowing.—Koerte⁴ says chronic pancreatitis may produce symptoms similar to those of obstruction of the duct, due to pressure by tumors, and that cholecystenterostomy relieves the condition. He reports 4 cases of obstruction of the duct, two were due to a chronic inflammatory condition and two were due

to carcinoma. Koerte says very often the obstruction is due to a fibrous stricture and it is taken to be due to malignant disease. Operation alone can clear up the matter. The origin of the stricture is obscure, but he believes an infection upon a catarrhal condition of the common duct is the true solution of the matter. In his first case he had an opportunity of studying the pancreatic juice; during fasting only 14 cc. to 18 cc. were secreted, but during digestion it gradually increased for 5 hours to 50 cc. The administration of sodium chlorid increased the secretion; the administration of fat had no effect. The secretion was found to split fat, but failed to split albumins without the addition of intestinal juice. Koerte particularly notes the high remittent fever and the continued pain, not colicky in character, in his first case. [J.F.]

Senile Calcification of the Vas Deferens and Seminal Vesicles.—H. Chiari¹ reports 3 cases of this localization of senile calcification, which has not been previously studied. The ampulla of the vas deferens is the part especially affected. The calcification occurs always in the connective tissue of the muscular coat, and is to be regarded as a pure retrogressive metamorphosis. It is preceded by an increase in the connective tissue, together with a sclerotic change in the same. The process must be distinguished from the thickening which results from chronic inflammation of these structures. [B.K.]

Points in Abdominal Diseases.—E. Stanmore Bishop² compares the inflamed abdominal cavity, or any portion of it, to an inflamed joint. In the latter, nature causes muscles surrounding it to become rigid in their efforts to immobilize the diseased tissues; similarly in the abdomen, if the peritoneum is inflamed, nature causes the protecting muscles to become rigid in their effort to produce immobility and rest. Abdominal rigidity he considers one of the most significant signs which we possess in making diagnosis of intraabdominal conditions. This occurs only when there is acute inflammatory condition of the peritoneum; it does not occur in the chronic forms, as in tuberculous peritonitis. He calls attention to the great fear of resulting peritonitis which we experience for the first few days after laparotomy. This can, in every case, be ruled out when it is found that the abdominal wall is flaccid and normal. In appendicitis, intussusception, strangulated hernia, etc., we have localized abdominal rigidity. Distension of the abdomen in obstruction is a sign that interference has reached a dangerous point, not so much because the gut is paralyzed but because of the stasis of the blood current in the vessels supplying the distended area, and gangrene may follow. In intussusception he emphasizes the difficulty of diagnosis in many instances, but the question of abdominal rigidity will always be of assistance. Hydrostatic treatment of this condition he condemns as a waste of time, and a most dangerous procedure, because, in many instances, the intussusceptum is practically screwed into the intussusciplens, and no reasonable amount of hydrostatic pressure can force it out; operation is the only procedure worthy of consideration. [A.B.C.]

Thrombosis and Embolism of the Mesenteric Vessels.—Falkenburg³ states that the clinical picture is nearly always that of an acute intestinal occlusion upon which peritonitis soon supervenes. In some cases the condition simulates perforation peritonitis and invagination of the intestine. With thrombosis and embolism of other organs and especially with failure of compensation, the same condition of the mesentery vessels may be suspected; upon these grounds he made the diagnosis in 2 cases, corroborated postmortem in 1. Operation in these cases is usually a failure, still he believes that in some cases laparotomy should be done, since small infarcts can be cured by intestinal resection. [A.B.C.]

Surgical Interference in Traumatic Liver Lesions.—W. N. Rosanoff⁴ considers operative aid in wound lesions of the liver tissue as absolutely necessary and justified *a priori* by the wellknown tendency of the liver to bleed profusely owing to its noncollapsible veins. According to statistics, most patients of this kind bleed to death inside of 24 hours if proper

¹ Arch. f. klin. Chir., Bd. lxxix, Heft 1, 1903.

⁴ Medizinskoje Obosrenie, ix, No. 17.

aid is not forthcoming. Hence in every case of wounded liver the hemorrhage must be stopped *in loco* by immediate interference. If any doubt exists as to the lesion, an exploratory laparotomy is indicated. Shock is hardly a contraindication to operating, as the danger of death from hemorrhage is so much greater than from shock. The diagnosis may be quite difficult, especially in subcutaneous rupture of the liver. Tension of the abdominal muscles, chiefly a rigidity of the recti, is a valuable sign of abdominal visceral wounds in general, and of liver injuries in particular. In recent years the reports of successful interference in liver trauma are becoming quite frequent. [L.J.]

Complete Suprapubic Prostatectomy.—Sir William J. Collins¹ reports that a man of 71 had suffered from enlarged prostate for several years, and during the past 2 years he had depended almost entirely on the catheter, his suffering being great. Under chloroform the bladder was irrigated and distended with boric lotion. A suprapubic incision exposed the bladder, and it was incised. A finger was introduced and the mucous membrane over the prostate stripped through. The prostate was then enucleated, and with the aid of 2 fingers in the rectum, it was detached and removed without further injury to the mucous membrane. Hemorrhage, which was not great, was controlled by hot boric solution. A large, rubber drainage-tube was made fast in the suprapubic wound, and a soft catheter in the urethra. For some 3 or 4 weeks, nearly all the urine was passed by the suprapubic wound, the catheter being left out on account of irritation after the fourth day. The patient soon began to improve in general health. In 36 days the suprapubic wound was entirely healed, and the patient remains cured of the condition. Sir William is of opinion that this, the Freyer method, is a safe, and in such cases most justifiable procedure. He adds a postscript which states that a similar operation has later been done on a man of 70, with equally good results. [A.B.C.]

Diverticulums of the Esophagus.—B. Fischer² reports several cases, and concludes that both pulsion and traction diverticulums of the esophagus may arise at times from a primary local inflammation, when the latter results in a scar. Pulsion diverticulums will be formed, especially if the scar be at a point where the greatest pressure is exerted, *i. e.*, at the narrowest parts of the esophagus. If the scar is adherent to surrounding tissues, a traction diverticulum may result from its shrinking. Injuries received in passing a stomach tube may give rise to diverticulums by the formation of scars. Pressure of surrounding structures plays a part in the development of diverticulums; hence the relative frequency of epiericoid, epibronchial, and epiphrenal diverticulums. [B.K.]

Pain and Tenderness in Inflammation of the Appendix.—Mansell Moullin³ says that since the alimentary canal is supplied by nerves which do not convey sensations of pain lesions of it, and of the visceral peritoneum, are painless; whereas inflammations of the parietal peritoneum and its subserous tissue are acutely painful. In reference to the appendix: 1. Absence of pain is no indication that serious mischief is not going on; the organ may have arrived at the stage of sloughing without pain. 2. The initial pain of acute appendicitis which is so commonly referred to the umbilicus is due to the peristaltic action of the cecum or appendix dragging upon the attachment of the peritoneum to the abdominal wall; it is most marked when the appendix is fixed by adhesions, or the mesentery is short or twisted. 3. Cessation of the umbilical pain without improvement in other symptoms is due to cessation of peristalsis caused by inflammation having spread to the muscular coat of the bowel, which prevents further contracting and therefore quiets the pain. 4. The development of local pain, which, as a rule, precedes the cessation of initial pain, means that the inflammation has spread from the appendix to the parietal peritoneum or its subserous tissue. Absence of local pain is without significance; severe pain is of serious import, as it implies inflammation wide-spread in extent or severe in degree. [A.B.C.]

REVIEW OF LITERATURE

The Therapeutic Use of Sea Voyages.—According to S. S. Cohen¹ the advantages of the ocean climate are its equability of temperature depending upon the radiation and absorption of the heat by the mass of water, the abundance of light, the freedom from dust and microbes and other impurities of the air, and the favorable atmospheric humidity. Aside from the climate, the prolonged rest and complete change of surroundings are important features in the curative effect of sea voyages. The disadvantages are the monotony, the cost, the poor ventilation of the cabins, the danger of poor food and the possibility of sea-sickness. Other things being equal, he prefers a sailing vessel to a steamship. Voyages of short duration are useful to give mental and physical rest, especially in convalescence from such depressing affections as influenza. Longer voyages of 1 or 2 months are useful in cases of neurasthenia, sometimes in asthma, in scrofulous conditions, and frequently in incipient pulmonary tuberculosis. Prolonged voyages, in which the vessel does not touch port are recommended only for those with high resistive power or for drug habitues. Sometimes the prolonged sea voyage is beneficial in pulmonary tuberculosis, as a restorative, or even in well-advanced cases as a palliative. Patients with severe cardiac disease should not take ocean trips at all. Those with far advanced tuberculosis, chronic gastrointestinal disorders, cholelithiasis, etc., should not take voyages of more than a week's duration. Neuralgic and gouty patients are frequently worse on sea than at home. [H.C.W.]

Catarrhal Jaundice and Cholelithiasis.—Kisch (Cronotherapy and Balneology, Blakiston, 1902) states that catarrhal jaundice, if it has not caused profound alterations and has existed for but a short time, often yields to the domestic employment of the alkaline acidulous waters of Bilin, Fachingen, Selters, and Gleichenberg. If, however, the jaundice has persisted for some time, and the liver is considerably enlarged, drinking-cures at Carlsbad, Ems, and Vichy, with the thermal waters of these places, are indicated, especially if the jaundice is attended with irritation of the lower portions of the intestinal tract, and diarrhea is accordingly present. Appropriate waters in the United States are those of Bedford (Magnesia) Springs, in Pennsylvania; Saratoga (Vichy) Springs, in New York; Greenbrier White Sulphur Springs and Irondale Springs, in West Virginia; Bedford Alum, Iron, and Lithia Springs, Rockbridge Alum Springs, and Bath Alum Springs, in Virginia; Bladon Springs, in Alabama. For full-blooded, strong, easily excitable individuals with jaundice, or when coprostasis is present, the cold waters of Marienbad, Kissingen, Homburg, and, in the United States, Saratoga, are to be preferred. The same differential indication is applicable in cases of gallstones, in which, as Frerichs had previously pointed out, complete courses of treatment at Carlsbad, Marienbad, Vichy, and Ems have proved the most effective remedy. This opinion, Kisch believes, remains completely sound at the present day, in spite of current operative tendencies. The waters may be used at the patient's home, or may be more effectively drunk at their source, for from 4 to 6 weeks. A considerable number of gallstones often is expelled as an immediate result. In order to prevent the formation of further concretions, the treatment should be repeated annually for several years. After operation in cases demanding surgical intervention, a similar course should be pursued.
